ABSTRACT

We present the first results of the application of supervised classification methods to the *Kepler* Q1 long-cadence light curves of a subsample of 2288 stars measured in the asteroseismology program of the mission. The methods, originally developed in the framework of the *CoRoT* and *Gaia* space missions, are capable of identifying the most common types of stellar variability in a reliable way. Many new variables have been discovered, among which a large fraction are eclipsing/ellipsoidal binaries unknown prior to launch. A comparison is made between our classification from the *Kepler* data and the pre-launch class based on data from the ground, showing that the latter needs significant improvement. The noise properties of the *Kepler* data are compared to those of the exoplanet program of the *CoRoT* satellite. We find that *Kepler* improves on *CoRoT* by a factor of 2–2.3 in point-to-point scatter.

Key words: binaries: eclipsing – methods: data analysis – methods: statistical – stars: variables: general – techniques: photometric

1. INTRODUCTION

The *Kepler* satellite, launched in 2009 March, is NASA’s first mission capable of finding Earth-size and smaller planets (Borucki et al. 2010; Koch et al. 2010). It has a 0.95 m aperture Schmidt telescope with a photometer comprised of 42 CCDs having a fixed field of view of 105 deg² in the constellations Cygnus and Lyrae. It is designed to monitor continuously the brightness of 160,000 stars during the first year, reduced to 100,000 stars later in the mission. This results in high-quality light curves, not only interesting for the detection of planets, but also of great importance for asteroseismology.

In this Letter, we present data from the asteroseismology program of the NASA *Kepler Mission* (Gilliland et al. 2010). We present a search for variable stars and the application of supervised classification methods to the *Kepler* long-cadence Q1 data of its asteroseismology program, covering 33.5 days in total. All the light curves have 29.4 minute time sampling. Both the total time span and the sampling are very well suited to study short-period eclipsing and ellipsoidal binaries, classical pulsators such as RR Lyrae (RR Lyr) stars and Cepheids, and nonradial pulsators such as β Cep stars, slowly pulsating B stars (SPBs), δ Sct stars, and γ Dor stars (see Aerts et al. 2010 for a definition of all these classes). We used the stellar fluxes as they were delivered to us after preliminary data processing (Jenkins et al. 2010). In total, we analyzed 2288 *Kepler* light curves.

We compare our results to a pre-launch classification based on data in the Kepler Input Catalog (KIC hereafter) and prepared by the Kepler Asteroseismic Science Consortium (KASC; Gilliland

et al. 2010). Finally, we compare the point-to-point scatter of the *Kepler* data to that of *CoRoT*’s exoplanet data of the first long run (5 months) of that mission.

2. ADOPTED METHODOLOGY

To detect and extract the variables, we relied on the automated variability characterization method as described in detail in Deboscher et al. (2007, 2009). This method searches for three independent frequencies for every star, which are used to make a harmonic best-fit to the trend-subtracted time series. In this way, we obtain a homogeneous set of parameters for each star, irrespective of its variability nature. The goal is *not* to achieve a good light-curve model, but rather to deduce a set of light-curve parameters that is sufficient to classify the variability.

Using this set of parameters, we classified the stars using a modified version of the classifier based on Gaussian mixtures, described in Deboscher et al. (2007), with the definition stars from Deboscher et al. (2009). We improved the performance of the algorithm presented in Deboscher et al. (2009) by classifying the objects using a multi-stage tree. In each node, we decide which groups of stars we want to distinguish. The best parameters are then selected for that node, and for each group the parameter distribution is approximated with a mixture of multi-dimensional Gaussians. To each variable stellar target we assign a probability that it belongs to a particular group.

In order to obtain the final probability for each variability class, we multiply the probabilities along the corresponding root-to-leaf path (see, e.g., Ripley 1996 for a general

Table 1
Stellar Variability Classes Considered in This Work

Stellar Variability Classes	MD < 3	MD < 2	MD < 3	KASC
			+ Visual Inspection	Pre-launch Class
Mira variables (MIRA)	0	0	0	305
RV Tauri stars (RVTAU)	1	1	0	2
Cepheids (CEP)	7	3	6	35
Compact pulsators (Compact)	-	-	-	4
RR Lyr stars (RRLYR)	28	28	28	51
β Cep or δ Sct stars (BCEP/DSCUT)	65	15	28	57
SPB or γ Dor stars (SPB/GDOR)	28	13	28	20
Ellipsoidal variables (ELL)	31	8	23	0
Eclipsing binaries (ECL)	101	92	101	100
Red giants (RG)	-	-	-	1513
Rapidly oscillating Ap stars (ROAP)	-	-	-	4
Oscillations in clusters (OS-clus)	-	-	-	178
Solar-like oscillations (SOL)	-	-	-	73

Notes. See Chapter 2 in Aerts et al. (2010) for a definition of the classes. MD stands for the Mahalanobis distance as defined in Debosscher et al. (2009). A hyphen “-” indicates variability types not taken into account in our classification scheme.

introduction and definition of tree-structured classifiers). In practice, this works as follows for our application: the probability of a stellar target being an RR Lyr star of type ab is, e.g., the probability of not being an eclipsing binary (first stage) times the probability of belonging to the RR Lyr group (second stage) times the probability of being an RR Lyr star of type ab.

This procedure was followed to compute class probabilities for each target. In order to obtain the best candidates, we additionally used the Mahalanobis distance, which is a multi-dimensional generalization of the one-dimensional statistical or standard distance as described in Debosscher et al. (2009). A visual check has been performed as well.

3. CLASSIFICATION RESULTS

The variability classes we currently take into account and the number of good candidate class members are listed in Table 1. While we securely classified more than 200 stars, the majority of targets still have a class assignment that is too ambiguous, mainly due to the limited time base and the large fraction of red giants among the samples (see below). Nevertheless, we managed to identify numerous new pulsators and binaries from the short time series and early data reduction. All the illustrations presented in this Letter contain stars that were either unknown as variables or were misclassified prior to launch.

We evaluated our classification results by visual inspection and manual analysis of the best candidates based on the Mahalanobis distance, and by comparing them with the pre-launch classification which is often insecure due to limited ground data. The results are summarized in Table 1. In the second and the third column, a Mahalanobis distance smaller than 3 and 2 is taken, respectively, without visual inspection. In the fourth column, the final numbers of candidates are given, taking a Mahalanobis distance less than 3 and performing an additional visual inspection. In the last column, the pre-launch classification done by KASC members is given. Note that several targets occur in more than one pre-launch class. For the majority of the classes in Table 1, our results appreciably improve the pre-launch results, which were necessarily based on ground-based data and could not take into account *Kepler*’s high-quality light curves. Good agreement is obtained for binaries and classical

pulsators such as RR Lyr stars and Cepheids, but even there, we are able to improve the pre-launch results as some RR Lyr candidates were reclassified by us as eclipsing binaries. One example is given in the third panel of Figure 1.

We could also identify many new (eclipsing) binaries, some of which are shown in Figure 1. An example of a red giant pulsator with solar-like oscillations in an eclipsing binary is discussed in detail in Hekker et al. (2010).

For main-sequence nonradial pulsators, such as β Cep, δ Sct, SPB, and γ Dor stars, there is much discrepancy between the pre-launch and our classification. Few of the pre-launch candidates turn out to be actual class members. Indeed, we do not find high-probability candidates among these stars with a pre-launch class assignment. On the other hand, we identified new nonradial pulsators not present in the pre-launch lists. Some examples are shown in Figure 2. Similar light curves, albeit for fainter stars, were found in the *CoRoT* exoplanet database (Degroote et al. 2009, e.g.).

We have not yet been able to compare our results for the long-period variables along or past the Asymptotic Giant Branch, such as Miras or RV Tauri stars, since the current total time span of the light curves is only a fraction of the typical pulsation periods of those objects. Moreover, we did not yet search for short-period pulsators, such as solar-like pulsators along the main sequence, rapidly oscillating Ap stars, subdwarf OB variables, and white dwarf pulsators (see Aerts et al. (2010) for class definitions), given that we do not yet have short-cadence data.

Another point of attention is the classification of solar-like pulsators. Stochastic pulsations are more easily recognized from a broad power excess than from the methodology adopted here. Indeed, the automated selection of the three highest frequency peaks will almost always result in peaks due to granulation and/or background noise. Thus, to find such pulsators, one better uses an extractor-type approach. This involves fitting and subtraction of the granulation and background signal to characterize the type of star, after which the oscillations can be sought. We refer to Chaplin et al. (2010), Bedding et al. (2010), and Stello et al. (2010) for a study of solar-like pulsators among *Kepler* targets.

Finally, we stress that our classifiers solely use the information contained in the *Kepler* light curves. This implies that we cannot discriminate well between the class pairs of B-type β Cep and

Figure 1. Some newly discovered eclipsing binaries, which were not identified as such prior to launch. The pre-launch KASC class is given on the right.

Figure 2. Some examples of multiperiodic pulsators, not present in the pre-launch class lists of pulsators. The pre-launch KASC class is given on the right.

Figure 3. Point-to-point scatter of the long-cadence light curves in *Kepler*'s asteroseismology program (Gilliland et al. 2010, black dots) compared to the one of the light curves in the *CoRoT* LRC01 exoplanet programme (Auvergne et al. 2009, gray crosses).

A-type δ Sct stars with periodicities of the order of hours, and B-type SPB versus F-type γ Dor stars with oscillation periods of days. Both pairs of classes contain light curves with very similar characteristics. To discriminate between them, at least some spectral information, such as a properly dereddened $B-V$ color index or a stellar spectrum, is needed. According to the initial mass function, most of these candidates should be AF-type pulsators.

4. NOISE PROPERTIES OF THE *KEPLER* DATA IN THE ASTEROSEISMOLOGY PROGRAM

Figure 3 reveals the point-to-point scatter in the *Kepler* data of its asteroseismology program as described in Gilliland et al. (2010), as well as a comparison with that for the *CoRoT* space mission's exoplanet data for its first long run of 5 months (Auvergne et al. 2009; Aigrain et al. 2009). We rescaled the *CoRoT* data to the same integration time of 29.4 minutes as for the long-cadence mode of *Kepler* in order to ensure an appropriate comparison. Duty cycles of these *CoRoT* and *Kepler* data are some 90% and 99%, respectively. It can be seen that the *Kepler* data with still preliminary processing (Jenkins et al. 2010) already outperform the *CoRoT* exoplanet data by a factor of ~ 2 for objects with a visual magnitude of around 14 to a factor of ~ 2.3 for objects of magnitude around 16. This is more or less as expected based on the difference in aperture size of the two instruments. Importantly for follow-up studies of the most interesting variable stars, the *Kepler* asteroseismology sample focuses on brighter objects.

Typical noise levels of the least variable stars in the *Kepler* asteroseismology program, estimated as the average amplitude in the Fourier transform avoiding the low-frequency regime below 1 cycle per day, range from $1.3 \mu\text{mag}$ for an 8th magnitude star to $34 \mu\text{mag}$ for a 16th magnitude star. More than 70 % of the KASC stars are variable in one way or another, even taking

into account residual instrumental effects. Note that this is a much higher fraction than for the *CoRoT* exoplanet program, because the KASC target selection was aimed at focusing on variable stars while the *CoRoT* exoplanet sample is unbiased with respect to variability.

5. CONCLUSIONS

We presented the first results of the application of automated supervised classification methods to 2288 *Kepler* light curves. Comparison with existing pre-launch classification and manual classification of the light curves shows the capabilities of our methodology: we are able to significantly improve the pre-existing classification results and to identify new class members, unknown prior to launch.

We will repeat the classifications as more and longer time-span light curves become available. This way, we will also be able to identify variables with longer periodicities and have much better capacity to unravel beat periods in multiperiodic pulsators. More classes will be included in the classification scheme, and, even more importantly, the class definition stars will be updated using the high-quality *Kepler* light curves themselves. Access to 1 minute cadence data will allow us to classify shorter period variables, in addition to those presented here. With each new set of data, our results will be updated and made available.

We thank the entire *Kepler* team, whose excellent efforts have made these results possible. Funding for this Discovery mission is provided by NASA's Science Mission Directorate. The research leading to these results has received funding from the European Research Council under the European Community's Seventh Framework Programme (FP7/2007–2013)/ERC grant agreement no. 227224 (PROSPERITY), as well as from the Research Council of K.U. Leuven grant agreement GOA/2008/04 and from the Belgian Federal Science Office. D.W.K. acknowledges support from the UK Science and Technology Facilities Council.
