NOREXIA nervosa is a severe psychiatric disorder with a prevalence up to 0.9% among young females, and according to the criteria of the Diagnostic and Statistical Manual of Mental Disorders–IV the average of the European studies is 0.29%. The incidence in a large representative sample in the Netherlands (1.1% of total population) was 8.1 per 100,000 per year. Females are affected more than males, and the female-to-male ratio is > 10:1. The 15- to 19-year age group represents the highest rate, constituting ~ 40% of all identified cases.

Despite intensive treatment programs (for example, with psycho- and/or pharmacotherapy), prospective long-term follow-up investigations reveal a poor outcome in a quarter of the patients. These patients continue to suffer or die due to suicide or physical complications associated with extreme starvation like dehydration and electrolyte imbalance. The mortality rates have been reported to be 3 and 15.6% after 5 and 21 years of follow-up, respectively.5,30 Functional neuroimaging and neuroendocrinological studies have provided substantial evidence for the involvement of the central nervous system in the mediation and maintenance of the symptoms in patients with anorexia nervosa.9 We therefore speculate that therapeutic interventions directed at the central nervous system, like electrical brain stimulation, may alleviate symptoms in patients suffering from treatment-resistant anorexia nervosa. Likewise, electrical brain stimulation has proven successful in patients suffering from treatment-resistant obsessive–compulsive disorder and major depression disorder, 2 psychiatric disorders related to anorexia nervosa.29,30 Because it is unknown in which brain targets electrical stimulation relieves symptoms, we rely on the activity-based anorexia

Electrical stimulation in the lateral hypothalamus in rats in the activity-based anorexia model

Laboratory investigation

Object. One quarter of patients with anorexia nervosa have a poor outcome and continue to suffer chronically or die. Electrical brain stimulation may be of therapeutic benefit in some of these patients; however, the brain target for inducing symptom relief is unknown. In this study, the authors evaluated the effects of acute and chronic electrical stimulation in the lateral hypothalamus on food intake, locomotor activity, and survival time in rats in an activity-based anorexia model.

Methods. In an acute experiment, the authors electrically stimulated at 100 Hz and 0, 25, 50 and 75% of the maximal stimulation amplitude (that is, the amplitude leading to severe side effects) in the lateral hypothalamus on consecutive days during 4 test sessions in 10 rats and evaluated food intake and locomotor activity. In a chronic experiment, they compared food intake, wheel revolutions, and survival time between 6 rats that underwent electrical stimulation in the lateral hypothalamus (50% of maximal stimulation amplitude) and 8 rats that did not undergo stimulation.

Results. In the acute experiment, overall electrical stimulation (25, 50, and 75% combined) and stimulation at 75% of the maximal stimulation amplitude significantly decreased the locomotor activity. However, if the authors omitted results of 1 rat, in which the electrode tip was not located in the lateral hypothalamus on one side but rather in the supraoptic chiasm, the remaining results did not yield significance. No other differences were observed.

Conclusions. When the findings of the current study are extrapolated to patients with anorexia nervosa, the authors do not expect major effects on symptoms with electrical stimulation at high frequency in the lateral hypothalamus. (DOI: 10.3171/FOC/2008/25/7/E7)

KEY WORDS • activity-based anorexia • anorexia nervosa • electrical brain stimulation • lateral hypothalamus
rat model to predict outcome of electrical stimulation in patients with anorexia nervosa.

In this model, the food intake of rats that can eat at libitum during 1.5 hours daily for several weeks is enough to maintain body weight. However, in the presence of a running wheel in the cage, these rats will display hyperactivity after 7 to 10 days and spontaneously restrict their food intake leading to severe emaciation and often even death. This behavior models some of the symptoms in patients with anorexia nervosa: dieting and excessive exercising. However, we are well aware that some other core symptoms, like the patient’s disturbance in the perception of body weight and shape, and the intense fear of gaining weight or becoming fat, are likely not present in the activity-based anorexia model.

The lateral hypothalamus plays a key role in the regulation of food intake and body weight homeostasis. In an acute experiment in rats in the activity-based anorexia model, we stimulated at 0, 25, 50 and 75% of the maximal stimulation amplitude, that is, the amplitude leading to severe side effects. We hypothesized that overall electrical stimulation (25, 50, and 75% combined) and stimulation at 75% of the maximal stimulation amplitude would reduce activity and increase food intake. Moreover, we hypothesized that the changes are stimulation-amplitude dependent. In a chronic experiment in rats in the activity-based anorexia model, we stimulated at 0 and 50% of the maximal stimulation amplitude, and hypothesized that stimulation at 50% of the maximal stimulation amplitude decreases hyperactivity, and increases food intake and survival time in rats in the activity-based anorexia model.

Methods

Test Animals

Twenty-six female albino Wistar rats, weighing 200–250 g at the start of the experiment, were housed 2 per cage before surgery and individually after surgery. They had free access to food before the start of the experiments in the activity-based anorexia model and to water at all times. All experiments were carried out in accordance with protocols approved by the local university animal ethics committee and in accordance with the European Communities Council Directive of November 24, 1986 (86/609/EEC).

Experimental Cages

Activity-based anorexia experiments were conducted in custom-made cages (0.36 x 0.36 x 0.36 m) with a running wheel (diameter 0.35 m; Campden Instruments). An electromagnetic rotary encoder (TWK-Elektronik GmbH) was mounted on the shaft of the running wheel for continuous registration of the position of the running wheel with a digital I/O card (National Instruments) and LabVIEW 7.0 (National Instruments).

Surgical Procedure

Amoxicillin (subcutaneous 0.4 ml; Duphramox, Intervet International B.V.) was prophylactically injected. After induction of general anesthesia (subcutaneous 400 mg/kg chloral hydrate; Sigma-Aldrich) the head was positioned in a stereotactic frame (Narishige) with the bregma and lambdoidal positioned in the horizontal plane. Lidocaine (subcutaneous 0.4 ml Xylocaine 2% 20 mg/ml, AstraZeneca SA) was administered locally before incising the skin. Monopolar 80% platinum/20% iridium stimulation electrodes (Goodfellow Cambridge Ltd.) with a diameter of 200 μm and a bare transversally cut tip were implanted bilaterally in the lateral hypothalamus (2.6 mm posterior to the bregma, 1.8 mm lateral to the midline, and 8.3 mm ventral to the dural surface) using the coordinates of the atlas of Paxinos and Watson. Self-tapping bone screws (Fine Science Tools) were inserted in the skull and served as reference electrodes and as anchor points to mount the cement block. This cement block kept the electrodes in position and externalized the connectors, which conducted the current in case of electrical stimulation.

Study Design

Acute Experiment. One week after implantation of the electrodes, 10 rats were placed in the activity-based anorexia test cages. When body weight decreased to 85% of the initial body weight (that is, the body weight when the animal was first placed in the experimental cage), the maximal stimulation amplitude was determined, and during subsequent days 4 test sessions were performed in random order with stimulation amplitude (independent variable) at 0, 25, 50, and 75% of the maximal stimulation amplitude. The dependent variables in the acute experiment were the number of revolutions in the running wheel during the 2 hours preceding the feeding period (9–11 a.m.) and food intake during the 1.5-hour feeding period. Body weight was measured every day, and a limited amount of extra food was provided daily after the test sessions to keep body weight at 85% of the initial body weight (1 g of food for every 1% below 85% of the initial body weight). The observer, who measured food intake and body weight, was blinded to the test condition.

Chronic Experiment. One week after implantation of the electrodes, rats were randomly allocated to the stimulation-on or -off group (8 rats/group) and subsequently placed in the experimental cages. When body weight decreased to 85% of the initial body weight, the maximal stimulation amplitude was determined in the stimulation-on group, and stimulation was started at 50% of the maximal stimulation amplitude in this group. This stimulation amplitude was chosen because minor side effects were sometimes observed at 75% of the maximal stimulation amplitude. The stimulation-off group was handled in the same manner, but electrical stimulation was not applied. The dependent variables in the chronic experiment were the daily number of rotations (measured continuously) and daily food intake during the 1.5-hour feeding period. In addition, we measured the number of days until the animal died or until body weight decreased to 70% of the initial body weight. When this occurred, experiments were terminated for that individual rat. Experiments were also terminated in case body weight remained constant or increased during 5 consecutive days (< 1% decrease in body weight compared with the previous day); the rat was considered not susceptible for activity-based anorexia. Rats that did not die were killed with an overdose of Nembutal. The observer, who measured food intake and body weight, was blinded to the test condition.
**Electrical Stimulation**

**Acute Experiment.** Constant current, biphasic, cathodic-first square wave pulses with a pulse width of 0.06 msec (1 unidirectional phase) were administered at a frequency of 100 Hz starting 2 hours before the food intake period and lasting 3.5 hours in total (9 a.m.–12.30 p.m.). The maximal stimulation amplitude (in mA) was the amplitude that clearly interfered with normal behavior.

**Chronic Experiment.** Electrical stimulation parameters were identical to those in the acute experiment except that electrical stimulation was applied continuously starting when the rat’s body weight decreased to lower than 85% of the initial body weight until the end of the experiment.

**Histological Analysis**

After the experiments, the rats were killed with an overdose of pentobarbital (intraperitoneal 3 ml Nembutal, CEVA Santé Animal) and the brains were removed and quickly frozen at (–40°C in 2-methylbutane (106056, Merck KgaA). Verification of the electrode tip location was performed in 25-μm cryostat sections stained with thionin (Janssen Chimica). The electrode tip was localized based on the atlas of Paxinos and Watson, taking into account the surrounding anatomy.

**Data Analysis**

**Acute Experiment.** Repeated measurement analysis was used to unravel the overall effect of electrical stimulation in the lateral hypothalamus on the number of rotations and food intake. Because data regarding the number of rotations and food intake at 75% of the maximal stimulation amplitude were missing in 1 animal, the procedure PROC MIXED was used instead of PROC GLM in the statistical software (version 9.1.2, SAS Institute Inc.). The paired Wilcoxon test was used to determine the effect of electrical stimulation at 75 versus 0% of the maximal stimulation amplitude.
Chronic Experiment. We searched for differences in the number of days until the animal died (or until body weight decreased to 70% of the initial body weight) between the stimulation-on and -off groups by using the log-rank test. The number of rotations and food intake were not analyzed as a function of time because it was not straightforward to describe this relationship with an appropriate parametric function. Indeed, circadian activity patterns varied considerably due to periods of sleep and food intake. Also, the group sizes were rather small to analyze the mean daily food intake and number of rotations in function of time. Therefore, we averaged the number of rotations and food intake for each animal and compared the mean number of rotations and food intake using Wilcoxon tests without taking time into account.

Results

Positioning of Electrode Tips

Based on the stereotactic rat atlas of Paxinos and Watson, all electrode tips were located in the lateral hypothalamus except in 1 rat in the acute experiment, in which the electrode tip was located in the supraoptic chiasm. A schematic representation of the position of the electrode tips is depicted in Figs. 1 and 2.

Submaximal and Maximal Stimulation Amplitude

At submaximal stimulation amplitudes, some rats displayed exploratory behavior, walking criss-cross around in the cage, sniffing at the floor and the walls, and sometimes rearing with both forepaws on the walls of the cage. In other rats, seemingly automated locomotor stepping with elevated forepaws, resembling marching, was observed. Finally, some rats commenced rapid locomotion in the periphery of the cage, often interrupted by upright postures and sometimes even jumping as if they wanted to escape out of the cage. Because food was absent during testing for maximal stimulation amplitude, eating was not observed. At maximal stimulation amplitudes, these behaviors were exaggerated and clearly interfered with normal behavior.
Lateral hypothalamus stimulation in the activity-based anorexia model

Acute Experiment

Raw data on the number of rotations and food intake for the different percentages of the maximal stimulation amplitude are represented respectively in Figs. 3 and 4. One value was missing unrelated to the intervention (electrical stimulation).

Overall electrical stimulation in the lateral hypothalamus (25, 50, and 75% of the maximal stimulation amplitude combined) induced a significant decrease of the number of rotations compared with 0% of the maximal stimulation amplitude (–467 ± 192, estimated difference (standard error, p < 0.04), however, without affecting food intake (–0.02 ± 0.60 g, p < 0.97).

Figure 3 gives the impression that the decrease in the number of rotations is amplitude-dependent; however, no significant difference between the number of rotations at 25, 50 and 75% of the maximal stimulation amplitude was observed (p < 0.39). Likewise, no significant difference was observed between food intake at 25, 50, and 75% of the maximal stimulation amplitude (p < 0.74; Fig. 4).

Paired Wilcoxon tests revealed a significant decrease of the number of rotations at 75% of the maximal stimulation amplitude compared with 0% (p < 0.04), but no difference for food intake (p < 0.93). However, if the data obtained from the rat with 1 electrode tip in the supraoptic chiasm were omitted, overall electrical stimulation no longer had a significant effect on the number of rotations (p < 0.07). Likewise, the number of rotations at 75% compared with 0% of the maximal stimulation amplitude was no longer significantly different (p < 0.08).

Chronic Experiment

Two rats from the stimulation-on group were excluded because their body weight remained constant during 5 consecutive days before reaching 85% of their initial body weight. For the remaining rats, the number of days after reaching 85% of the initial body weight until the end of the experiment (as defined above) was 4.5 ± 3.9 days in the stimulation-on group and 4.8 ± 2.0 days in the stimulation-off group. Of note, body weight of 1 rat in the stimulation-on group remained constant during 5 consecutive days. Therefore this rat was considered a survivor (censored). The log-rank test revealed no significant differences for the number of days between both groups (p < 0.57).

Electrical stimulation neither had an effect on the number of wheel revolutions preceding the feeding period (stimulation on 111 ± 67 rotations/hour, stimulation off 128 ± 87 rotations/hour, mean ± standard deviation; p < 0.30, Fig. 5) nor on the food intake per day during the 1.5-hour feeding period (stimulation on 5.4 ± 4.5 g, stimulation off 7.8 ± 4.1 g, mean ± standard deviation; p < 0.22 [Fig. 6]).

Discussion

Activity-Based Anorexia Model

Rats in the activity-based anorexia model, which were fed at libitum for 1.5 hours a day and had continuous access to a running wheel, were not able to sustain their body weight and even died.14,30 Only a minority of the rats were resistant to this procedure and survived (8–12% of our sample). In the current experiment, the daily distance in the running wheel was up to 10.7 km after 1 to 2 weeks in some rats, with a daily food intake on average between 5 and 15 g for the acute and chronic experiment, both in accordance with previous experiments.9

Validity of the Model

Animal models for psychiatric disorders provide a valuable tool for developing new treatments. The models need to be subjected to strict validating criteria, including face, predictive, and construct validity.49 Johansen and Schalling49 concluded in their review that the activity-based
anorexia model has a better face and construct validity than other models for anorexia nervosa. The authors were, however, reserved in attributing predictive validity to the models due to the lack of potent pharmacological agents for treating patients with anorexia nervosa. The effect of cyproheptadine, which has some modest benefit during the weight restoration phase in patients with anorexia nervosa, has not been evaluated in the activity-based anorexia model. Fluoxetine has a comparable effect in patients with anorexia nervosa and in the activity-based anorexia model: during the weight maintenance phase the relapse rate may decrease in patients with anorexia nervosa and it induces a decrease in wheel running and an increase in food intake in the activity-based anorexia model. Also, increasing the environmental temperature in patients with anorexia nervosa as well as in rats in the activity-based anorexia model was reported to have beneficial effects. Finally, discriminant validity was raised as a fourth additional criterion for animal models for psychiatric disorders. The model should specifically point to anorexia nervosa as distinct from different psychiatric disorders. The activity-based anorexia model was mainly used as a model for anorexia nervosa, although it has also been used as a model for gastric ulcers (as reported by Paré and Temple) and has been proposed as a model for obsessive–compulsive disorder. However, this does not deprecate the value of the activity-based anorexia model as a model for anorexia nervosa because ulcers are present in 16% of the patients with anorexia nervosa, and obsessive–compulsive disorder is related to and often comorbid with anorexia nervosa.

Neuroanatomy of the Lateral Hypothalamus

The lateral hypothalamus plays a key role within a distributed neural network that controls the regulation of food intake and body weight. It has efferent projections to the entire cortical mantle, hippocampus, extended amygdala, basal ganglia and thalamus, the midbrain and pons, the brainstem and spinal cord, as well as most other nuclei of the hypothalamus. Afferents originate from various cortical/limbic areas such as the prefrontal/orbitofrontal, insular, and olfactory cortex, amygdalar cortex, hippocampus, and the ventral striatum, including the nucleus accumbens. Most of the connections to the brainstem and midbrain areas are reciprocal.

The Hypothalamus and the Activity-Based Anorexia Model

Alterations in local neurotransmitter levels provide direct evidence for the involvement of the hypothalamus in the activity-based anorexia model. Noradrenergic, histaminergic, and dopaminergic neuronal activity in the hypothalamus are significantly enhanced while serotonergic metabolism was decreased. Additional indirect evidence for the involvement of the hypothalamus comes from the increased activity of the hypothalamic–pituitary adrenal axis in this model. Some authors evaluated the effect of specific interventions in subregions of the hypothalamus on behavior in the activity-based anorexia model. A kainic lesion in the ventromedial hypothalamus decreased activity in the running wheel and body weight loss was decelerated, but this did not affect food intake. On the contrary, a lesion in the suprachiasmatic nucleus of the hypothalamus had no effect and local administration of clonidine, an α2 noradrenergic receptor agonist, in the paraventricular hypothalamus even decreased food intake and survival in rats in the activity-based anorexia model. In normal rats, however, a recent study demonstrated weight loss after chronic electrical stimulation in the lateral hypothalamus.

Acute Experiment

Activity. At submaximal and maximal electrical stimulation in the lateral hypothalamus, we observed an initiation of automated stepping and increased exploratory and escape behavior, which is in agreement with the observations of other authors. The descending course of the pathway mediating locomotion elicited by electrical stimulation of the lateral hypothalamus is known to involve the ventral tegmental area and the red nucleus in the anteromedial ventral tegmentum and the pedunculopontine nucleus, the pontis oralis nucleus, and the region around the superior cerebellar peduncle more posterior in the mesencephalon.

Electrical stimulation in the lateral hypothalamus in the activity-based anorexia experiment significantly reduced...
wheel-running. However, our findings were no longer significant after omission of the data of 1 rat. Of note, the electrode tip was on one side in the supraoptic chiasm but abutting the lateral hypothalamus (< 0.2 mm, Fig. 1), and the current likely spread into the lateral hypothalamus. Moreover, the electrode tip on the other side was well positioned in the lateral hypothalamus. Likely, a decrease in power may explain our findings.

**Food Intake.** Rather unexpectedly, we observed no significant effect of acute electrical stimulation in the lateral hypothalamus on food intake in rats in the activity-based anorexia model. Nevertheless, electrical stimulation in the lateral hypothalamus may induce feelings of hunger, as reported by obese patients during acute electrical stimulation experiments in the lateral hypothalamus before making a lesion.23 In rats, electrical stimulation in the lateral hypothalamus induces an eating response and a significant increase in the amount of food intake.26–27 The target for electrical stimulation in our experiments was derived from one of those experiments in which a large number of rats responded with an increase in food intake. It is also unlikely that the severe state of emaciation in the activity-based anorexia model is the reason that electrical stimulation had no effect on our experiment. Indeed, it has been demonstrated that electrical stimulation in the lateral hypothalamus in rats that were deprived of food for 72 hours has a larger effect on food intake than electrical stimulation or deprivation separately.26,27 Likewise, in rats with amphetamine-induced appetite suppression, electrical stimulation in the lateral hypothalamus increased food intake.28

**Chronic Experiment**

Both the activity in the running wheel and food intake were unaffected in our chronic experiment, although we observed a decrease in activity in our acute experiment. It may be that electrical stimulation has only a temporary effect on activity or that the stimulation amplitude needs to be raised to sustain the effect on activity. However, the latter argument is contradicted by the findings of our acute experiment, in which we observed no difference in activity between electrical stimulation with 25, 50, or 75% of the maximal stimulation amplitude. Another explanation is that the activity in the running wheel in our acute experiment was replaced by activity in the rest of the cage with no effect on global activity as the net result. Given that we did not record activity in the rest of the cage, this hypothesis cannot be excluded.

As both hyperactivity and a decrease in food intake are the main determinants for a bad outcome in the activity-based anorexia model, we observed no effect on survival time after chronic electrical stimulation in the lateral hypothalamus.

**Neurosurgery in Patients With Anorexia Nervosa**

In several patients suffering from severe anorexia nervosa, the effect of surgical lesions in different brain regions (for example, leucotomy,28 dorsomedial thalamotomy,25 and so on) was investigated, and most of the studies demonstrated a poor outcome on core symptoms. Moreover, lesions are irreversible, a disadvantage in case severe side effects occur. Therefore, we opted for investigating the effects of electrical brain stimulation, which is a reversible technique. As far as we know, electrical brain stimulation in only 1 patient suffering from anorexia nervosa has been published.29 She had a 12-year history of anorexia nervosa, was completely amenorrheic, and had to be tube-fed. Electrical stimulation on the cerebellar cortex induced a pleasant and relaxed feeling, and reduced associated compulsive rituals. Her menstrual cycle returned to normal but she still continued to refuse eating.

**Study Limitations**

In the current experiments, we preferred to work with female rats because the incidence of anorexia nervosa in humans is more than 10 times higher in females than males. However, in female rats, food intake and wheel running fluctuated with the estrous cycle, resulting in a higher day-to-day variability and decreasing the likeliness to observe small effect sizes. We did not synchronize the estrous cycle with the day of introduction in the activity-based anorexia model.

The size of the groups is rather limited, especially the size of the stimulation-on group in the chronic experiment (6 rats). However, the findings of the acute and the chronic experiments are in agreement with each other and are not indicative for major differences.

We did not record the activity of the rats in the rest of the cages (for example, by measuring the number of infrared beam crossings); it is unknown whether the decrease in activity observed in our acute experiment is generalized.

**Conclusions**

Electrical stimulation in the lateral hypothalamus decreased hyperactivity during acute but not chronic electrical stimulation, with no effect on food intake and survival time. Although extrapolation of findings in animal experiments to humans is not straightforward, especially in psychiatric disorders, we do not expect that electrical stimulation in the lateral hypothalamus will affect symptoms in patients suffering from anorexia nervosa.
