Abstract: In this note we study the problem of estimating the parameters of the conditional median function at elliptical models. For this we use positive-breakdown estimators of multivariate location and scatter, and obtain influence functions and asymptotic variances of the resulting slope and intercept. We also consider a technique to gain efficiency by artificially increasing the dimension.

Key words: Elliptical Model, Median, Regression, Robustness.

1 Introduction

Let x be a p -variate explanatory variable and y a univariate response variable. Denote $z = (x^t, y)$ and suppose that z is distributed according to an elliptically symmetric distribution H . The density h of H can then be expressed as

$$h(x) = \frac{1}{(\det \Sigma)^{1/2}} g((z - \mu)^t \Sigma^{-1} (z - \mu))$$

where g is a real-valued function, $\mu \in \mathbb{R}^{p+1}$ is called the location parameter, and the parameter $\Sigma \in \text{PDS}(p+1)$ is called the scatter matrix. Here $\text{PDS}(p+1)$ is the set of positive definite symmetric matrices of size $p+1$. We can decompose μ and Σ as

$$\mu = \begin{bmatrix} \mu_x \\ \mu_y \end{bmatrix} \quad \text{and} \quad \Sigma = \begin{bmatrix} \Sigma_{xx} & \Sigma_{xy} \\ \Sigma_{yx} & \Sigma_{yy} \end{bmatrix},$$

and similarly for estimators $\hat{\mu}_n$ and $\hat{\Sigma}_n$ of μ and Σ . It follows from Proposition 13.1 of Bilodeau and Brenner (1999, page 208) that the conditional distribution of y given x is symmetric with median

$$m(x) := \text{med}(y|x) = \alpha + \beta^t x \tag{1}$$

where

$$\beta = \Sigma_{xx}^{-1} \Sigma_{xy} \quad \text{and} \quad \alpha = \mu_y - \beta^t \mu_x. \tag{2}$$

Since we did not assume that H has a first moment, the conditional mean $E[y|x]$ need not exist. Note that (1) can be rewritten as a linear regression equation

$$y = \alpha + \beta^t x + \varepsilon \tag{3}$$

where the distribution of the error term $\varepsilon := y - m(x)$ is symmetric about zero. In general this distribution depends on x , so (3) is a heteroscedastic regression model. The only H for which the distribution of ε does not depend on x is the multivariate normal (see e.g. Fang, Kotz and Ng 1990, page 106). In that case ε has a univariate gaussian distribution with constant scale, hence (3) becomes homoscedastic.

For any elliptical distribution H it follows from (1) that the conditional median function $m(x)$ is linear, so it is natural to estimate it by

$$\hat{m}_n(x) := \hat{\alpha}_n + \hat{\beta}_n^t x \tag{4}$$

with

$$\hat{\beta}_n = \hat{\Sigma}_{n,xx}^{-1} \hat{\Sigma}_{n,xy} \quad \text{and} \quad \hat{\alpha}_n = \hat{\mu}_{n,y} - \hat{\beta}_n^t \hat{\mu}_{n,x}. \quad (5)$$

In this way, every estimator $(\hat{\mu}_n, \hat{\Sigma}_n)$ of multivariate location and scatter leads to an immediate estimate of the conditional median function. When $E_H(|Y|) < \infty$ it holds that $m(x) = E[y|x]$, so then $\hat{m}_n(x)$ also estimates the conditional mean function.

The classical estimator of (μ, Σ) is the empirical mean and covariance matrix. For an i.i.d. sample $z_1, \dots, z_n$ from H , with $z_i = (x_i^t, y_i)$, they are given by

$$\hat{\mu}_n = \frac{1}{n} \sum_{i=1}^n z_i \quad \text{and} \quad \hat{\Sigma}_n = \frac{1}{n} \sum_{i=1}^n (z_i - \hat{\mu}_n)(z_i - \hat{\mu}_n)^t.$$

The corresponding $\hat{\alpha}_n$ and $\hat{\beta}_n$ as given by (5) can then easily be shown to coincide with the least squares regression estimator of y on x . This is a highly nonrobust procedure, since it is known that the least squares estimator can become completely corrupted by even a single outlier. Therefore we prefer to insert a robust estimator of multivariate location and scatter instead. Many such estimators have been proposed (see Maronna and Yohai 1998 for an overview). We will require them to be affine equivariant and asymptotically normal. Maronna and Morgenthaler (1986) inserted M-estimators of multivariate location and scatter, and showed that the resulting estimators $\hat{\alpha}_n$ and $\hat{\beta}_n$ have all the desired equivariance properties. However, it is known that the breakdown value of multivariate M-estimators goes down like $1/p$.

In this paper we will focus on estimators of (μ, Σ) that have a high breakdown value, such as the Minimum Covariance Determinant estimator (MCD) of Rousseeuw (1984). For a finite sample of observations $z_1, \dots, z_n$ in $\mathbb{R}^{p+1}$, the MCD is determined by selecting that subset $\{z_{i_1}, \dots, z_{i_h}\}$ of size h , with $1 \leq h \leq n$, which minimizes the generalized variance (which is the determinant of the covariance matrix computed from the subset) among all possible subsets of size h . The location estimator is then defined as

$$\hat{\mu}_n = \frac{1}{h} \sum_{j=1}^h z_{i_j}$$

and the scatter estimator by

$$\hat{\Sigma}_n = c_p \frac{1}{h} \sum_{j=1}^h (z_{i_j} - \hat{\mu}_n)(z_{i_j} - \hat{\mu}_n)^t \quad (6)$$

where c_p is a consistency factor. The choice $h = \lceil (n + p + 1)/2 \rceil \approx 0.5n$ yields the highest possible breakdown value. The commonly preferred default value is $h \approx 0.75n$, yielding a better compromise between efficiency and breakdown value.

In Section 2 of this paper we compute the influence function of the estimators of α and β based on robust estimators of location and scatter. In Section 3 we see that the efficiency of the estimators depends on the number of explanatory variables. This fact can be exploited to slightly increase the efficiency by artificially augmenting the dimension.

2 Influence Function

The influence function (IF) measures the effect of a small amount of outliers on an estimator (Hampel et al, 1986). Before deriving influence functions we need to define the functionals corresponding to $\hat{\alpha}_n$ and $\hat{\beta}_n$. Let G be an arbitrary $(p + 1)$ dimensional distribution and $(T(G), C(G)) \in \mathbb{R}^{p+1} \times PDS(p + 1)$ the location/scatter functional evaluated at G . For instance, an S-estimator (see Rousseeuw and Leroy 1987, page 263) can be defined as a functional, and for finite samples we put $\hat{\mu}_n := T(H_n)$ and $\hat{\Sigma}_n := C(H_n)$ where H_n is the empirical distribution function of the data. We now decompose

$$T(G) = \begin{bmatrix} T_x(G) \\ T_y(G) \end{bmatrix} \quad \text{and} \quad C(G) = \begin{bmatrix} C_{xx}(G) & C_{xy}(G) \\ C_{yx}(G) & C_{yy}(G) \end{bmatrix}.$$

The functionals of interest are then

$$b(G) = C_{xx}(G)^{-1}C_{xy}(G) \tag{7}$$

and

$$a(G) = T_y(G) - b(G)^t T_x(G). \tag{8}$$

By definition, a Fisher-consistent location/scatter functional satisfies $T(H) = \mu$ and $C(H) = \Sigma$ at the model distribution H , yielding

$$b(H) = \beta \quad \text{and} \quad a(H) = \alpha.$$

At the empirical distribution function H_n we put $\hat{\beta}_n = b(H_n)$ and $\hat{\alpha}_n = a(H_n)$.

The influence function of b at the model distribution H is defined as

$$\text{IF}(z, b, H) = \frac{\partial}{\partial \varepsilon} b((1 - \varepsilon)H + \varepsilon \Delta_z) \Big|_{\varepsilon = 0}$$

where Δ_z represents a Dirac measure putting all its mass at $z = (x^t, y) \in \mathbb{R}^{p+1}$, and $\text{IF}(z, a, H)$ is defined analogously. Since we require that T and C be affine equivariant, we may suppose without loss of generality that $\mu = 0$ and $\Sigma = I_{p+1}$ which yields $\alpha = 0$ and $\beta = 0$. If T and C possess an influence function, then by Lemma 2 of Croux and Haesbroeck (2000) we know that two real-valued functions γ and δ exist such that

$$\text{IF}(z, C, H) = \gamma(z^t z) z^t z - \delta(z^t z) I_{p+1}. \quad (9)$$

Furthermore, there exists a third real-valued function ζ such that

$$\text{IF}(z, T, H) = \zeta(z^t z) z. \quad (10)$$

We will express the influence function of the slope and intercept in terms of γ and ζ .

Proposition 1 *At the model distribution H with $\mu = 0$ and $\Sigma = I_{p+1}$ it holds that*

$$\text{IF}(z, b, H) = \gamma(z^t z) xy \quad \text{and} \quad \text{IF}(z, a, H) = \zeta(z^t z) y$$

with $z = (x^t, y)$.

Proof: This follows from applying the chain rule to (7) and (8) and filling in (9) and (10), because

$$\begin{aligned} \text{IF}(z, b, H) &= C_{xx}(H)^{-1} \text{IF}(z, C_{xy}, H) + \text{IF}(z, C_{xx}^{-1}, H) C_{xy}(H) \\ &= \text{IF}(z, C_{xy}, H) = \gamma(z^t z) xy \end{aligned}$$

and

$$\begin{aligned} \text{IF}(z, a, H) &= \text{IF}(z, T_y, H) - \text{IF}(z, b, H)^t T_x(H) - b(H)^t \text{IF}(z, T_x, H) \\ &= \text{IF}(z, T_y, H) = \zeta(z^t z) y \end{aligned}$$

where the standardizations $C(H) = I_{p+1}$ and $T(H) = 0$ were used. $\square$

For S-estimators of multivariate location and scatter the functions γ, δ and ζ are given by Lopuhaä (1989), and for the MCD estimator they can be retrieved from Butler, Davies, and Jhun (1993) and Croux and Haesbroeck (1999a). Lopuhaä (1999) gives expressions for the reweighted versions of these estimators. It then follows directly from Proposition 1 that the influence functions of the slope and intercept based on these estimators will be bounded, by filling in their functions γ and ζ . For instance, for the MCD estimator with trimming

proportion τ (i.e. with coverage $h \approx (1 - \tau)n$) we obtain simple explicit formulas for γ and ζ :

$$\gamma_{\text{MCD}}(t) = \frac{I(t \leq \sqrt{q_\tau})}{\Gamma(\frac{p}{2} + 2, \frac{q_\tau}{2})} \quad \text{and} \quad \zeta_{\text{MCD}}(t) = \frac{I(t \leq \sqrt{q_\tau})}{\Gamma(\frac{p}{2} + 1, \frac{q_\tau}{2})} \quad (11)$$

were $q_\tau = \chi_{p+1, 1-\tau}^2$ and $\Gamma(u, v) = \int_0^v \frac{e^{-t} t^{u-1}}{\Gamma(u)} dt$ is the incomplete gamma function. The influence functions of a and b based on the MCD approach can thus be seen as truncated versions of the Least Squares influence functions (where $\gamma \equiv \zeta \equiv 1$). In the center of the distribution both $\text{IF}(z, b, \text{MCD})$ and $\text{IF}(z, a, \text{MCD})$ are similar to their classical counterparts, but observations far from the center (i.e. with large $z^t z$) will receive a zero influence.

3 Efficiency Considerations

For S -estimators and the MCD it holds that

$$\sqrt{n}(\hat{\mu}_n - \mu) \xrightarrow{d} N(0, \text{ASV}(T, H))$$

with asymptotic (co-)variance $\text{ASV}(T, H) = E_H[\text{IF}(z, T, H)\text{IF}(z, T, H)^t]$, and similarly for the scatter estimator $\hat{\Sigma}$. Since $\hat{\beta}$ is a differentiable function of the elements of $\hat{\Sigma}$, the estimator $\hat{\beta}$ will also be asymptotically normal with $\text{ASV}(b, H) = E_H[\text{IF}(z, b, H)\text{IF}(z, b, H)^t]$, and similarly for $\hat{a}$. This leads to

Proposition 2 *At the model distribution H with $\mu = 0$ and $\Sigma = I_{p+1}$ we have*

$$\text{ASV}(b, H) = \left(\int \gamma^2(z^t z) y^2 x_1^2 dH(x, y) \right) I_p$$

and

$$\text{ASV}(a, H) = \int \zeta^2(z^t z) y^2 dH(x, y)$$

From (9) and (10) one can easily verify that $\text{ASV}(b, H) = \text{ASV}(C_{xy}, H)$ and $\text{ASV}(a, H) = \text{ASV}(T_y, H)$. Therefore, the efficiency of the slope estimator equals that of the off-diagonal elements of the scatter matrix estimator, and the intercept estimator $\hat{a}_n$ inherits the efficiency of the location estimator.

Expressions for the asymptotic variances of the MCD-based functionals have been computed in the Gaussian case (Croux and Haesbroeck, 1999a). In Figure 1 we see how

Figure 1: $ASV(b, H)$ and $ASV(a, H)$ for the slope and intercept functionals based on the MCD with trimming proportion 25%, as a function of p and for $H = N(0, I_{p+1})$.

Table 1: Simulated bias and MSE for the slope and intercept estimators of the conditional median function at the bivariate normal model for several sample sizes. The estimates are based on the MCD estimator and on the MCD+1 and MCD+3 procedures.

		$\hat{\beta}$			$\hat{\alpha}$

	n*MSE	5.7326	5.2264	4.4659	2.5204	2.5204	2.5607
100	bias	-0.0057	-0.0010	0.0053	0.0007	0.0010	0.0027
	n*MSE	5.5339	4.5309	3.3948	2.3747	2.2689	2.1411
200	bias	0.0086	0.0079	0.0056	-0.0024	-0.0017	0.0000
	n*MSE	6.7878	4.8495	3.4645	2.3401	2.1985	1.8538
∞	bias	0	0	0	0	0	0
	n*MSE	6.1350	4.2918	3.0864	2.4788	2.1456	1.8828

these asymptotic variances decrease with the number of explanatory variables. (The matrix $ASV(b, H)$ is represented by one of its diagonal elements). Note that for the classical estimator these asymptotic variances are independent of the dimension and equal to one.

A surprising consequence of this increasing efficiency is that adding explanatory variables will increase the precision of the slope and intercept estimators. These extra variables may even be randomly generated. This technique is illustrated in the following simulation experiment, where we are interested in estimating the conditional median function for (x, y) distributed according to a bivariate normal distribution H :

$$\text{median}(y|x) = \alpha + \beta x. \quad (12)$$

A total of $m = 1000$ samples of size n was generated from $H = N(0, I_2)$ (we take $\Sigma = I_2$ w.l.o.g. due to equivariance properties). For each sample, estimates $\hat{\alpha}_n^j$ and $\hat{\beta}_n^j$ based on the MCD with $h = \lfloor \frac{3}{4}n \rfloor$ were computed, using the FAST-MCD algorithm of Rousseeuw and Van Driessen (1999). The simulated bias is defined as $\frac{1}{m} \sum_{j=1}^m \hat{\beta}_m^j - \beta$, and the mean squared error (MSE) as $\frac{1}{m} \sum_{j=1}^m (\hat{\beta}_m^j - \beta)^2$. Similar definitions apply for the intercept. From Table 1 we see that the biases are negligible, while the efficiencies at finite samples are relatively close to their asymptotic counterparts for $n \geq 50$.

The same simulation has been repeated for what will be called the MCD+1 procedure. Here we generated an extra variable $v \sim N(0, 1)$ independently of x and y . By estimating the parameters of the equation

$$\text{median}(y|x) = \text{median}(y|x, v) = \alpha_1 + \beta_1 x + \beta_2 v$$

using the three-dimensional MCD location/scatter estimator we obtain $\hat{\beta}_1$ and $\hat{\beta}_2$. We set $\hat{\alpha} := \hat{\alpha}_1$ (since the parameter α in (12) equals α_1) and $\hat{\beta} := \hat{\beta}_1$, and we discard $\hat{\beta}_2$. The estimator MCD+3 is defined similarly, and requires computation of the MCD in 5 dimensions. From Table 1 we see that adding the variable v did decrease the mean squared error at not-too-small finite samples ($n \geq 50$ for the slope and $n \geq 100$ for the intercept). This decrease is smaller for the intercept than for the slope, and we see from Figure 1 that the gain in asymptotic efficiency for the intercept is indeed less substantial. Note that the breakdown value of MCD, MCD+1 and MCD+3 remains unchanged at 25%.

The question which arises is what price we have paid for this increase in efficiency. One would expect an increase in the bias of the estimators. Therefore, in each generated sample

Table 2: As in Table 1, but with 20% of extreme outliers.

		$\hat{\beta}$			$\hat{\alpha}$

50	bias	0.6248	0.5229	0.4142	0.1329	0.1505	0.1677
	n*MSE	22.8656	17.5709	12.8190	5.9116	5.2684	5.1440
100	bias	0.5987	0.5095	0.4155	0.1446	0.1686	0.1845
	n*MSE	38.7552	29.2909	20.4300	6.6277	6.3930	6.2680
200	bias	0.5957	0.5153	0.4241	0.1517	0.1697	0.1834
	n*MSE	74.1416	56.5352	39.1476	9.5074	9.4878	9.4194

we replaced 20% of the observations by outliers (x_i, y_i) generated from the contaminating distribution $N_2((5, 5)^t, \text{diag}(0.1, 0.1))$. The resulting biases and MSEs are given in Table 2. We again see a decrease of the MSE, but now only for $n \geq 100$ for the slope and $n \geq 200$ for the intercept. It is remarkable that all the biases remain negligible, and that the MSEs under contamination turn out to be even better than the MSEs when no outliers are present. This is because the MCD estimator has a redescending influence function so that far away outliers are harmless, and therefore applying the MCD with $1 - \tau = 75\%$ to data with 20% of far outliers is like applying the MCD with $1 - \tau = 75\%/80\% = 93.75\%$ to a (smaller) data set without outliers.

It was shown by Croux and Haesbroeck (1999b) that intermediate outliers are more harmful than extreme outliers, so we conducted a third experiment where the outliers are generated from the distribution $N_2((\sqrt{q/2}, \sqrt{q/2})^t, \text{diag}(0.1, 0.1))$, with $q = \chi_{2,0.75}^2$ the upper 25% quantile of the χ_2^2 distribution. We see that the results for the slope parameter improve when the dimension is increased, but for the intercept the MSEs remain similar.

To conclude this simulation experiment, we could say that adding artificially generated random variables increases the efficiency of the estimator for sample sizes which are not too small, without loss of robustness. This increase in efficiency is substantial for small p , but for problems with moderate to high p the effect will practically disappear, since already at the asymptotic level the gain becomes very small (see Figure 1). Of course, one should not forget that the computational effort increases with every added variable.
