Introduction: During locomotion, vestibular feedback is essential in maintaining dynamic stability through adjusting the timing and magnitude of foot placements¹. Additionally, vestibular feedback regulates the head movements and provides a stable gaze during walking². In case of a complete or partial vestibular function loss, as found in bilateral vestibulopathy (BV) patients, an increased postural imbalance during standing and walking is noted which is associated with an increased risk of falling³. Additionally, gaze stability is reduced⁴. To investigate the effect of vestibular loss on locomotion in BV-patients, the gait performance of these patients was compared with that of healthy adults and correlated to performance on a functional balance test.

Research question: How does bilateral vestibular loss affect gait performance?

Methods: An instrumented gait analysis was performed in a convenience sample of nine *BV-patients* and nine *age- and sex-matched healthy adults*, randomly selected from an existing database. All subjects walked barefoot overground at self-selected walking speed. Additionally, BV-patients performed the Tinetti-test and completed the Dizziness Handicap Index (DHI). Mean walking speed, stride and step time (s), -length (m), step width (m) and stance (%) were selected as outcome variables, as well as their variability expressed as standard deviations (SD). Differences between left and right spatio-temporal parameters (STP) were investigated with the Wilcoxon Signed Rank test, and as no significant differences were found ($p=[0.086;0.953]$), the data were pooled for further analysis. Between group differences were analyzed using the Mann-Whitney U test. Correlations between Tinetti (sub)scores and STP were calculated with the Spearman's rho.

Results: Subject characteristics are presented in Table 1. Significant differences in step width (m), stride time SD (s), step time SD (s) and stance SD (%) were noted (Table 2). A worse performance of the Tinetti-test was correlated with a greater gait variability ($r=[-0.503;-0.851]$) and a shorter stride and step length ($r=0.557;r=0.537$) (Table 3).

Discussion: Up until now, information about the effects of bilateral vestibular function loss on gait performance is lacking. Our results, although preliminary, were similar to those of Pradhan et al. where BV-patients had a slower walking speed, wider base of support, shorter stride length and an increased stride time variability as compared to healthy controls. These gait alterations could indicate a more cautious way of walking, due to loss of vestibular feedback resulting in postural imbalance³, and act as a way to increase the dynamic walking stability⁶. Further investigation of gait characteristics in a large cohort of BV-patients is advised in order to fully understand the alterations in gait performance due to bilateral vestibular function loss.
