Abstract

- 1. Meta-analyses in ecology and evolution require special attention due to certain study characteristics in these fields. First, the primary articles in these fields usually report results that are observed from studies conducted with different species, and the phylogeny among the species violates the independence assumption. Second, articles frequently allow the computation of multiple effect sizes which cannot be accounted for by conventional meta-analytic models. While both issues can be dealt with by utilizing a multilevel model that accounts for phylogeny, the performance of such a model has not been examined extensively. In this article, we investigate the performance of this model in comparison with some simpler models.
- 2. We conducted an extensive simulation study where data with different hierarchical structures (in terms of study and species levels) were generated and then various models were fitted to examine their performance. The models we used include the conventional random effects and multilevel random-effects models along with more complex multilevel models that account for species-level variance with different variance components. Furthermore, we present an illustrative application of these models based on the data from a meta-analysis on sizeassortative mating and comment on the results in light of the findings from the simulation study.
- 3. Our simulation results show that, when the phylogenetic relationships among the species are at least moderately strong, only the most complex model that decomposes the species-level variance into nonphylogenetic and phylogenetic components provides approximately unbiased estimates of the overall mean and variance components and yields confidence intervals with an approximately nominal coverage rate. Contrarily, removing the phylogenetic or non-phylogenetic component leads to biased variance component estimates and an increased risk for incorrect inferences about the overall mean. These findings are supported by the results derived from the illustrative application.
- 4. Based on our results, we suggest that meta-analyses in ecology and evolution should use the model that accounts for both the nonphylogenetic and phylogenetic species-level variance in addition to the multilevel structure of the data. Any attempts to simplify this model, such as using only the phylogenetic variance component, may lead to erroneous inferences from the data.

1 | INTRODUCTION

384

Meta-analysis encompasses an array of methods for synthesizing information from studies examining some phenomenon of interest and evaluating the consistency of their results (Cooper et al., 2009; Glass, 1976; Hedges & Olkin, 1985; Senior et al., 2016). Although these methods have been mostly developed in the medical and social sciences (Cooper et al., 2009; Egger et al., 2001; Sutton & Higgins, 2008), ecologists and evolutionary biologists have successfully adopted these techniques for conducting research syntheses in their respective fields (Gurevitch et al., 2001, 2018; Koricheva et al., 2013). However, meta-analyses in ecology and evolution typically have several features that require special attention so that trustworthy evidence can be obtained.

To start, meta-analyses in these fields often incorporate data from multiple species which share an evolutionary history, described by a phylogeny (Arnqvist & Wooster, 1995; Chamberlain et al., 2012; Gurevitch & Hedges, 1999). As a result, the samples (and the effect sizes obtained from these samples) are not independent which violates the independence assumption underlying conventional meta-analytic models. For example, the standard fixed- and random-effects models (Hedges & Olkin, 1985; Hedges & Vevea, 1998), often used for ecological meta-analyses (Nakagawa & Santos, 2012), assume independence among the effect sizes and therefore do not account for phylogeny (Chamberlain et al., 2012; Noble et al., 2017). This issue was first addressed by Adams (2008) and Lajeunesse (2009) who incorporated phylogenies into the fixed- and random-effects models, respectively.

Chamberlain et al. (2012) empirically investigated how the inclusion of phylogeny affects the estimate of the overall mean based on data from 30 meta-analyses in ecology and evolution. While the estimate of the overall mean did not change considerably in most cases (especially when using a random-effects model), a substantial portion of the meta-analyses, which reported significant results before, produced non-significant results when the phylogeny was incorporated into the model. Therefore, including phylogeny might be an important factor to reduce Type I error rates and to obtain an accurate reflection of the uncertainty of meta-analytic estimates.

Although Chamberlain et al.'s (2012) study is the most extensive study to date examining the effects of phylogeny in meta-analysis, their work was based on available meta-analyses. To investigate the issue of phylogeny more broadly, we require a simulation study to explore a wider parameter space and under controlled conditions. Moreover, Chamberlain et al. (2012) did not address the fact that ecological and evolutionary studies usually report multiple effect sizes per study, which leads to dependence among the effect sizes belonging to the same study (Nakagawa & Santos, 2012;

Noble et al., 2017). Although past and current meta-analyses have sometimes avoided this issue by selecting a single effect size from each study or by collapsing multiple effect sizes into one, these procedures can lead to a severe loss of information (Nakagawa & Santos, 2012; Nakagawa et al., 2021).

As an alternative, Hadfield and Nakagawa (2010) proposed a mixed-effects model that accounts for the multilevel structure via a study-level random effect (i.e. multiple effect sizes per study are nested within this random effect). In the same model, they include two additional random effects to estimate the non-phylogenetic and the phylogenetic species-level variance. This way, among-species variance is decomposed into two components, the one resulting from species similarities due to evolutionary history and the other from species similarities due to shared ecology and other factors (Lynch, 1991). Although the model by Hadfield and Nakagawa (2010) addresses two major statistical issues in ecological and evolutionary meta-analyses, the complexity of the model poses certain challenges.

Partitioning the species variance into its two components is a challenging endeavour, because both components are modelled using random effects at the species level, with the only difference being that the phylogenetic component assumes that the random effects are correlated according to a phylogenetic correlation matrix—which is derived from a phylogenetic tree constructed based on the similarities and differences of species in terms of their (usually) genetic (but sometimes also physical) characteristics (Felsenstein, 2004). This raises concerns about the identifiability of the variance components and potential bias in their estimates, and issues that have also been raised outside the meta-analytic context when analysing the data of primary studies including multiple species (Paradis, 2012).

Moreover, the complexity of the model poses a threat to the convergence of optimization algorithms (Bates et al., 2015). Accordingly, Nakagawa and Santos (2012) suggested that model fitting may only be feasible with larger datasets, which would limit the applicability of the model in practice. To avoid these problems, some ecological and evolutionary meta-analyses have been carried out using a simplified model without the non-phylogenetic random effect and that therefore accounts for species variance only via the phylogenetic component (e.g. Garamszegi et al., 2012; Moore et al., 2016). However, the consequences of doing so, and the performance of the more complex model, have yet to be evaluated in a simulation study.

We therefore investigated the performance of models for conducting a phylogenetic multilevel meta-analysis in a comprehensive simulation study. We simulate studies that report multiple effect sizes and use several models that vary in their complexity, starting from a simple model (including only a random effect at the effect sizes level) to the most complex model which incorporates a

study-level and two among-species random effects. Furthermore, we generate specific conditions to examine the performance of the most complex model when phylogenetic relationships are weak and the consequences of removing the non-phylogenetic component. Finally, we present an illustrative application of these models based on the data from a meta-analysis on size-assortative mating and comment on the results in light of the findings from the simulation study.

2 | MATERIALS AND METHODS

2.1 | Meta-analytic models

To conduct a meta-analysis, the phenomenon of interest (e.g. the size of a treatment effect or the strength of the association between two variables) needs to be quantified in terms of an effect size estimate for each study to be included in the analysis. We use the term 'study' broadly here (and essentially in the sense of 'paper' or 'publication'), as a single study may contribute multiple estimates (i.e. multiple effect sizes, for instance, for multiple species, subgroups, treatments), but for the moment we assume that each study contributes a single estimate to the meta-analysis. Depending on the purpose of a metaanalysis and the information reported in the individual studies, one might use raw or standardized mean differences, response ratios, odds/risk ratios or correlation coefficients to quantify the relevant results (see Borenstein et al., 2011, for a review). In addition, we need to compute the sampling variances of the estimates, that is, the variability in each estimate that would be expected under repeated sampling of new study units under identical circumstances (Borenstein et al., 2011; Cooper et al., 2009; Nakagawa & Cuthill, 2007).

Regardless of the specific measure used in a meta-analysis, let y_i denote the effect size estimate for the ith study (with $i=1,...,N_{\text{studies}}$) and v_i the corresponding sampling variance (note that the terms 'study' and 'effect size' are interchangeable when each study reports a single effect size). The most basic model that can be considered for synthesizing the estimates is the fixed-effects model, which is given by

$$y_i = \mu + e_i, \tag{1}$$

$$e \sim N(0, \mathbf{V}),$$
 (2)

where μ is the overall mean, e_i is the sampling error for the ith study, \mathbf{e} is a $1 \times N_{\text{studies}}$ column vector with the e_i values (which are assumed to be normally distributed with mean 0 and variance v_i), $\mathbf{0}$ is a column vector of zeros and \mathbf{V} is an $N_{\text{studies}} \times N_{\text{studies}}$ matrix with the v_i values along the diagonal.

The fixed-effects model assumes that the included studies share a single common true effect. This assumption, however, is rarely met in multi-population and multi-species meta-analyses of ecology and evolution studies (Senior et al., 2016). The random-effects model addresses this potential 'heterogeneity' among the true effects by

adding a random effect corresponding to each estimate and is given by

$$y_i = \mu + u_i + e_i, \tag{3}$$

385

$$\mathbf{u} \sim N\left(0, \sigma_{u}^{2} \mathbf{I}_{u}\right),\tag{4}$$

where u_i is the random effect corresponding to the ith estimate, \mathbf{u} is a $1 \times N_{\text{studies}}$ column vector with the u_i values (which are assumed to be normally distributed with mean 0 and variance σ_u^2) and \mathbf{I}_u is an $N_{\text{studies}} \times N_{\text{studies}}$ identity matrix.

Although the models above are suitable for conducting a metaanalysis in many circumstances, they do not account for the multilevel structure that arises when at least some studies provide multiple effect size estimates (e.g. when the same experiment was conducted under varying circumstances within the same study) and they do not account for phylogenetic dependence (when studies are conducted with multiple species that differ in similarity due to differences in their shared evolutionary history).

To address the first issue, we can use a multilevel meta-analytic model (Konstantopoulos, 2011; Nakagawa & Santos, 2012) which includes a random effect at the effect size level (as in model 3—for brevity, we use the equation numbers to refer to the various models throughout this article), but which now captures variability in the true effects within studies, and a random effect at the study level, which captures between-study variability. Let y_{ij} denote the jth effect in the th study (with $j=1,...,N_i$, where N_i is the number of effect sizes reported in the jth study, j the corresponding sampling variance, and let j0 the study j1 denote the total number of effects. The model is then given by

$$y_{ii} = \mu + u_{ii} + s_i + e_{ii}, \tag{5}$$

$$s \sim N(0, \sigma_c^2 \mathbf{I}_s),$$
 (6)

where u_{ij} is a random effect corresponding to the jth effect size in the ith study, s_i is a random effect at the study level, \mathbf{u} is now a $1 \times N_{\text{total}}$ column vector with the u_{ij} values, s is a $1 \times N_{\text{studies}}$ column vector with the s_i values (which are assumed to be normally distributed with mean 0 and variance σ_s^2), and \mathbf{I}_u and \mathbf{I}_s are $N_{\text{total}} \times N_{\text{total}}$ and $N_{\text{studies}} \times N_{\text{studies}}$ identity matrices, respectively. Finally, \mathbf{e} is now a $1 \times N_{\text{total}}$ column vector with the e_{ij} values and \mathbf{V} is the corresponding (diagonal) variance—covariance matrix with dimensions $N_{\text{total}} \times N_{\text{total}}$, and the remaining terms are defined as described earlier.

When the effect size estimates are computed based on a set of $N_{\rm species}$ different species, we will need an additional index. Let y_{ijk} denote the jth effect in the ith study as before, but now let $k=1,...,N_{\rm species}$ be the index that indicates for which species a particular effect size estimate was computed. Model 5 can then be extended to account for species-level variability as follows:

$$y_{ijk} = \mu + u_{ij} + s_i + n_k + e_{ij},$$
 (7)

$$\mathbf{n} \sim N\left(0, \sigma_n^2 \mathbf{I}_n\right),\tag{8}$$

where n_k is a species-specific random effect, \mathbf{n} is a $1 \times N_{\text{species}}$ column vector with the n_k values (which are assumed to be normally distributed with mean 0 and between-species variance σ_n^2) and \mathbf{I}_n has dimensions $N_{\text{species}} \times N_{\text{species}}$, with the remaining terms as defined earlier. Note that n_k is a crossed random effect (e.g. Fernández-Castilla et al., 2019) and not nested within studies and we therefore do not put subscript k on u_{ii} , s_i or e_{ii} .

386

Model 7, however, does not account for phylogeny. For this, we further extend the model by including an additional species-level random effect (Hadfield & Nakagawa, 2010), but instead of assuming independence for different species (as for the n_k values), we allow the values of the random effect to be correlated according to a phylogenetic correlation matrix, which, in turn, is derived from a phylogenetic tree based on some model of evolution (e.g. Brownian motion) prior to the analysis (e.g. Felsenstein, 1985, 2004; Freckleton et al., 2002; Lajeunesse, 2009). The model is given by

$$y_{ijk} = \mu + u_{ij} + s_i + n_k + p_k + e_{ij},$$
 (9)

$$\mathbf{p} \sim N\left(0, \sigma_p^2 \mathbf{A}\right),\tag{10}$$

where p_k denotes the phylogenetic random effect for the kth species, p is a $1 \times N_{\rm species}$ column vector with the p_k values (which are assumed to follow a multivariate normal distribution with mean 0 and variance-covariance matrix $\sigma_p^2 A$, where σ_p^2 denotes between-species variance due to the phylogeny, and A is the $N_{\rm species} \times N_{\rm species}$ phylogenetic correlation matrix), with the remaining terms as defined earlier. Hence, the model includes a non-phylogenetic species-level random effect (i.e. the n_k values) to account for heterogeneity in the effect sizes due to differences between species unrelated to phylogeny (e.g. the influence of differences in the environments they live in) and a phylogenetic random effect (i.e. the p_k values) that captures dependencies in the effect sizes according to the similarities between species due to phylogenetic relatedness.

Since model 9 includes the species random effect twice (once assumed to be independent and once assumed to be correlated according to the values in **A**), concerns about identifiability and potential bias in the estimates of the variance components may be raised. In fact, when phylogenetic relationships are weak (i.e. when the off-diagonal values in **A** are close to 0 and hence the phylogenetic tree resembles a star phylogeny), then **A** starts to approximate I_n and hence σ_p^2 and σ_n^2 are confounded and are not uniquely identifiable. This concern, or the complexity of model 9 in general, has led some researchers to adopt a simplified model in their meta-analyses where the non-phylogenetic variance component is removed. This leads to the model

$$y_{ijk} = \mu + u_{ij} + s_i + p_k + e_{ij},$$
 (11)

with all terms as explained before. Whether this simplified version is an adequate substitute for model 9 is currently unknown.

The models described above can be fitted with the metafor package (Viechtbauer, 2010) for R (R Core Team, 2021). Maximum likelihood (ML) or restricted maximum likelihood (REML) estimation can be used for model fitting (the latter usually being the preferred choice; see Patterson & Thompson, 1971), providing estimates of the

variance components included in a particular model, the estimate of μ (i.e. $\widehat{\mu}$), and its standard error (i.e. $SE[\widehat{\mu}]$). Likelihood ratio tests and profile likelihood confidence intervals provide inferences for the variance components. An approximate 95% Wald-type confidence interval for μ can be obtained with $\widehat{\mu} \pm t_{.975,df}SE[\widehat{\mu}]$, where $t_{.975,df}$ denotes the 97.5th percentile of a t-distribution with df degrees of freedom. Based on Nakagawa et al. (2021), we set $df = N_{\rm studies} - 1$, which we expected would bring the coverage rate of the confidence interval closer to its nominal 95% level (when compared to a confidence interval based on a standard normal distribution).

Although fitting the models and deriving inferences from them are feasible, the consequences of using the various models have not been examined systematically. We therefore conducted an extensive simulation study to investigate the performance of the various model under varying circumstances.

2.2 | Simulation setup

In our setup, the primary studies could provide one or multiple effect size estimates for one or multiple species. We set ($N_{\rm studies}$, $N_{\rm species}$) either to (20, 40) or (50, 100) to examine the difference between a smaller versus larger meta-analysis. Furthermore, we set σ_u^2 , σ_s^2 , σ_n^2 and σ_p^2 to either 0, 0.05 or 0.3 (plus an additional parameter α to be described below to either 0.5, 1 or 2) to define a particular condition within the simulation study. Table 1 provides an overview of the 158 conditions that were studied in this manner. Note that, instead of a full factorization of all parameters, we introduced the variance components successively (in the order of σ_u^2 , σ_s^2 , σ_n^2 and σ_p^2) using the non-zero values (i.e. 0.05 and 0.3) to keep the number of conditions manageable and to generate scenarios where one of the models described in Equations 3, 5, 7 and 9 corresponds to the true data generating mechanism (see Table 1). Within a particular condition, the following steps were repeated 1,000 times.

First, the number of effect sizes provided by the studies (i.e. the N_i values) were simulated from a right-skewed distribution, as typically observed in practice. For this, we generated $N_{\rm studies}$ random values from a Beta(1.5,3) distribution, which were then multiplied by 39, rounded to the closest integer, and increased by 1. Therefore, the number of estimates per study could vary between 1 and 40 (with a mean, median and mode of approximately 14, 13 and 9, respectively).

In the next step, we simulated the species indices (i.e. the k values) by generating $N_{\rm total}$ random values from a Beta(2,2) distribution, which were multiplied by $N_{\rm species}-1$, rounded to the closest integer, and then increased by 1. Accordingly, the number of times that the various species were studied followed a symmetric unimodal distribution (with mean equal to $(N_{\rm species}+1)/2$). To guarantee that all species appear at least once in each meta-analysis, a randomly chosen $N_{\rm species}$ random numbers generated this way were replaced with the integers from 1 to $N_{\rm species}$.

Next, we generated a phylogenetic tree for the species using the rtree() function from the R package ape (Paradis & Schliep, 2019), which uses a recursive random splitting algorithm to simulate a

TABLE 1 Overview of the conditions examined in the mulation study. The first two columns show the number of studies and species, respectively. The next four columns indicate the true values of the variance components. The α column represents the power parameter. All values were crossed within a particular row of the table. The last two columns, respectively, indicate the number of conditions generated in each row and the model that corresponds to the true data generating mechanism for the conditions in a particular row

| N _{studies} | N _{species} | σ_u^2 | $\sigma_{_{\scriptscriptstyle S}}^{2}$ | σ_n^2 | σ_p^2 | α | Conditions | True model |

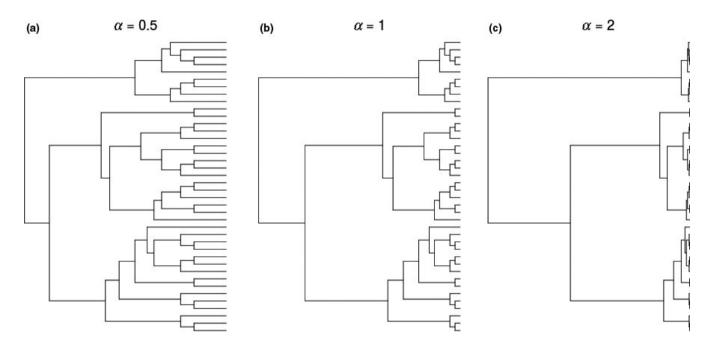

FIGURE 1 An example of a simulated phylogenetic tree for 40 species modified with different values of the power parameter α (i.e. 0.5, 1 and 2)

phylogeny (Paradis, 2012). The branch lengths were then computed using the <code>compute.brlen()</code> function based on the method by Grafen (1989), using the power parameter α to adjust the 'height' of branch lengths at the tips of the phylogenetic tree, leading to phylogenetic relationships that are generally stronger when branches are shorter at the tips or weaker when branches are longer at the tips. Figure 1 shows an example of such a simulated tree for 40 species modified by different α values. Finally, the correlation matrix that represents the phylogenetic relationships (matrix \mathbf{A} in Equation 10) was calculated from the tree by using the <code>vcv()</code> function based on a Brownian model of evolution (i.e. $\mathbf{A}_{k,k'} = \mathbf{1} - b_{k,k'}$, where $b_{k,k'}$ is the branch length for a pair of species to their most recent common ancestor). Hence, as α decreases, the off-diagonal values in \mathbf{A} converge to 0, whereas as α increases, the off-diagonal values in \mathbf{A} increase on average.

We then generated the values for the four random effects, corresponding to the variance components $\sigma_{u'}^2$, σ_s^2 , σ_n^2 and σ_p^2 , either as independent draws from normal distributions for the first three components or from a multivariate normal distribution for the last one. In conditions where a variance component is equal to 0, the corresponding random effect values are then just a series of 0s of the appropriate length. To complete the data generating step, the sampling variances (i.e. the v_{ij} values) were simulated from a right-skewed Beta(2,20) distribution (and hence had a value of 0.091 on average) which were then used to generate the N_{total} sampling errors from a normal distribution with mean 0 and variance v_{ij} . We then summed the random effects and sampling errors as shown in Equation 9, setting $\mu=0$ without loss of generality (as scalar changes to μ do not affect any other parts of the models).

387

After generating the data, we fitted the four models shown in Equations 3, 5, 7 and 9, using REML estimation as implemented in the rma.mv() function from the metafor package. For model 3, we simply treated each estimate as a separate study (one can also think of this as model 5 without the addition of the study-level random effect). For each model, we then saved the estimate of μ , the variance component estimates, the bounds of the 95% Wald-type confidence interval for μ , and the model fitting time to assess how demanding the computations are when fitting these models. In case any one of the four models did not converge within a particular iteration (with the default settings of the rma.mv() function), the iteration was discarded and a new iteration was run to guarantee that a 1,000 successful model fits were available for all four models (in all conditions, >99% of the analyses converged on solutions).

388

After the 1,000 iterations, we computed the mean of the $\hat{\mu}$ values for each model, the mean of the variance component estimates, the proportion of iterations where 0 was included in the confidence interval (i.e. the empirical coverage rate for μ), the mean confidence interval width, the mean absolute bias in the estimates of μ and the variance components, the convergence rate, and the mean model fitting time. The simulation was run on a workstation with two AMD EPYC 7551 32-Core CPUs utilizing 60 cores in parallel. Completion time for the simulation was approximately 35 hr (roughly 2,100 core hours).

We generated two other sets of conditions to investigate specific questions. First, we examined conditions where the phylogenetic relationships could also be weaker than in the main scenarios to test the performance of model 9 under such conditions. These conditions were generated by setting α to (0.1, 0.2, 0.3, 0.4, 0.5, 1, 2) when $(N_{\text{studies}}, N_{\text{species}}) = (50, 100)$, the estimate- and study-level variance components were both large (0.3), and the levels of the remaining variance components were factorized with values of 0.05 and 0.3 (for a total of 28 different conditions). Second, we compared the performance of model 9 and the simplified model 11 (that leaves out the non-phylogenetic species-level random effect). For this, we set (N_{studies}, N_{species}) = (50, 100), $\sigma_u^2 = 0.05$, $\sigma_s^2 = 0.05$ and $\alpha = 1$, and then generated different conditions by factorizing different values of only σ_n^2 and σ_n^2 , where the former was set to values from 0 to 0.3 with increments of 0.05, whereas the latter was set to either 0, 0.05 or 0.3 (for a total of 21 different conditions). The R code to reproduce the simulation and its results are available at the Open Science Framework (https://osf.io/ms8eg/).

3 | RESULTS

3.1 | Simulation results

Figure 2a displays boxplots of the mean $\hat{\mu}$ values (over the 1,000 iterations) for each of the four models across the 158 conditions, separated by which model was the true data generating mechanism. Generally, the means were clustered tightly around 0, indicating little to no bias in $\hat{\mu}$, although in a small set of conditions there was some slight positive bias in the estimates of the overall mean.

These conditions were characterized by non-zero values for all four variance components (i.e. when model 9 was the true model), $(N_{\text{studies}}, N_{\text{species}}) = (20, 40)$, a weak phylogenetic relationship ($\alpha = 0.5$) and a large phylogenetic variance ($\sigma_n^2 = 0.3$).

In contrast to the results for the overall mean, the coverage rates of the 95% confidence interval for μ differed markedly across models (Figure 2b). For conditions where model 3 was the true data generating mechanism, all models achieved coverage rates close to or slightly above the nominal 95% confidence level regardless of the condition. As the other variance components were introduced into the data, however, the coverage rates of models that did not account for these additional sources of variability started to decrease, at times severely so. Only model 9 was able to achieve rates close to the nominal level across the majority of conditions, although the rates also fell somewhat below the nominal level for certain conditions when all variance components were larger than zero.

Given that estimates of μ were relatively unbiased for all models, the closer to nominal coverage rates of model 9 would be expected to be mainly a consequence of wider confidence intervals (that consequently have a better chance of capturing the true value of μ). Figure 2c confirms this, showing the mean confidence interval widths for the various models across the various conditions. However, what is particularly noteworthy is that the use of model 9 under conditions where actually a simpler model is the true data generating mechanism only leads to a relatively minor increase in the mean interval width.

Figure 3 displays the bias in the variance component estimates of model 9 under the 28 different conditions generated by varying α , σ_n^2 and σ_p^2 (while holding σ_u^2 and σ_s^2 constant at 0.3). The results show no bias in the estimates of σ_u^2 and σ_s^2 . Furthermore, the model is able to estimate σ_n^2 and σ_p^2 with little to no bias, except when the strength of the phylogenetic relationships decreased. As expected, under such conditions, the model struggles to provide unbiased estimates of the non-phylogenetic and phylogenetic species-level variance components. Regardless, model 9 still provided overall estimates with mean absolute bias lower than 0.024 across all 28 conditions, although the coverage rate of the CI for μ again tended to fall somewhat below the nominal 95% level (with a mean coverage rate of 92% over the 28 conditions).

Figure 4a shows the coverage rates of the confidence interval for μ for models 9 and 11 as the size of the non-phylogenetic species-level variance component (i.e. σ_n^2) was increased. While model 9 provided rates close to or somewhat below the nominal level, the rates for model 11 were often equal to 100% and hence the confidence interval tended to be too wide (except for the three conditions where $\sigma_n^2=0$ and hence where model 11 was the true model). Furthermore, Figure 4b demonstrates that the bias in the phylogenetic variance component of model 11 inflated rapidly as the value of σ_n^2 increased (the value of σ_p^2 had no noteworthy influence on the bias and hence we averaged these results over the three possible values of σ_p^2). In contrast, model 9 estimated these two variance components essentially without bias under these scenarios.

Model fitting times differed between the various models (Table 2), with model 9 requiring the most amount of time on

average, regardless of the true data generating mechanism. The most challenging conditions for the more complex models were those scenarios where model 3 corresponded to the true data generating mechanism. In this case, a single fit of model 9 took around 33 s on average when $(N_{\text{studies}}, N_{\text{species}}) = (50, 100)$. In these conditions, convergence rates were also the lowest, although even model 9 then converged in more than 99% of the iterations.

3.2 | Illustrative example

We use the data from the meta-analysis by Rios Moura et al. (2021) on size-assortative mating (SAM) to illustrate an application of the models. Each study included in the meta-analysis provided one or

multiple correlation coefficients describing the similarity in some measure of body size in mating couples. For the analysis, the correlation coefficients were transformed with Fisher's *r*-to-*z* transformation (i.e. the inverse hyperbolic tangent transformation). We focus here on the estimate of the overall mean (transformed) correlation coefficient, leaving aside the issue of differences between studies where correlations were computed with or without pooling of data across different timepoints or areas (i.e. temporal/spatial pooling). Also, using the method by Grafen (1989), we turned the phylogenetic tree used by Rios Moura et al. (2021) into an ultrametric tree before fitting models 9 and 11, to bring these analyses more in line with how our simulation study was conducted. The dataset includes 1,828 effect size estimates (i.e. transformed correlations) collected from 457 studies and 341 species.

Table 3 presents the results obtained from each model. Interestingly, the estimate of the overall mean tended to be somewhat larger in the more complex models, although differences between models 7, 9 and 11 were relatively small. More importantly, we see a substantial increase in the standard error of the estimated overall mean for the more complex models. As a result, the confidence intervals become wider, the values of the test statistics were smaller, while the respective *p*-values increase. Although each model suggests that the overall mean significantly differs from 0 (at the conventional 0.05 level of significance), the *p*-value for model 11 was approaching the rejection threshold.

The estimates of the variance components also show some interesting patterns. While the simple random-effects model 3 cannot distinguish between different sources of variability and attributes all of the heterogeneity to differences between the individual effect size estimates, model 5 suggests that the variance in the effects is more related to differences between studies than particular estimates within studies. However, once species-level variability is considered in model 7, it becomes apparent that this is actually the dominant source of heterogeneity. Moreover, model 9 shows that this variability is approximately equally attributable to nonphylogenetic and phylogenetic species-level differences. In contrast, when ignoring the non-phylogenetic variance component in the simplified model 11, part of the variance from that component is forced back into the study-level variance component. Furthermore, $\hat{\sigma}_n^2$ in the simplified model is substantially inflated compared to model 9 which may be an example of the inflation in this component when σ_n^2 is excluded (see Figure 4b). Based on these findings and the Akaike Information Criteria (AIC) values of the various models, we would strongly favour model 9 in this comparison, illustrating that both non-phylogenetic and phylogenetic variance components should be considered in the analysis.

4 | DISCUSSION

Meta-analyses in the fields of ecology and evolution typically need to address the fact that multiple effect size estimates can be extracted from at least some of the studies and that the estimates are based on various species that are related to each other due to their shared evolutionary history. In this paper, we investigated the performance of the phylogenetic multilevel meta-analytic model by Hadfield and Nakagawa (2010) and Nakagawa and Santos (2012) that captures these intricacies along with some simpler models. Despite the concerns raised in the introduction, the model can successfully estimate the overall mean and its uncertainty. It also provides approximately unbiased estimates of all variance components, including the non-phylogenetic and phylogenetic specieslevel variances, as long as there are at least moderately strong phylogenetic relationships among the species. In addition, despite its complexity, the model does not appear to suffer from convergence problems and model fitting does not require excessive computational times.

TABLE 3 Results derived from fitting the various models to the example dataset. The first five columns show the estimated overall mean, its standard error, the 95% confidence interval, the test statistic and the p-value for testing H_0 : $\mu = 0$, respectively. The next four columns show the estimates of the variance components in the respective models. The last column shows the Akaike Information Criteria (AIC) values

4.1 | Estimating the overall mean and its uncertainty

392

Not only the phylogenetic multilevel meta-analytic model, but also the simpler models that leave out certain variance components provide essentially unbiased estimates of the overall mean, regardless of the nature of the true model that underlies the data (Figure 2a). However, the uncertainty in the overall mean will only be estimated accurately when the fitted model includes the variance components that contribute to the heterogeneity and the dependencies among the underlying true effects. Fitting underspecified models typically led to severe undercoverage of the confidence interval for the overall mean and hence anticonservative inferences. In fact, subtracting the coverage rates shown in Figure 2b from 1 yields the Type I error rates for the test of the overall mean, which could go as high as 91% when using a simple random-effects model that ignores the multilevel structure and the species-level variance components.

These findings are in line with those by Chamberlain et al. (2012), who demonstrated, based on 30 published meta-analyses, that the inclusion of phylogeny into a random-effects model usually only led to minor changes in the pooled effect size, but had a more substantial impact on the statistical significance of the finding (turning significant findings into non-significant ones in the majority of cases where changes occurred).

Our findings can also be used to alleviate concerns with using the phylogenetic multilevel meta-analytic model when it is actually an overspecified model (i.e. when the actual data generating mechanism is simpler). In those cases, the mean confidence interval width of the model was just barely wider than that of the simpler models, indicating little to no loss in efficiency by fitting an overly complex model (Figure 2c). The superfluous variance components then converge towards 0 (or close to it), which appears to be slightly more challenging for the optimization algorithm, leading to longer model fitting times and occasional convergence problems, but not to any worrisome degree (Table 2). Moreover, in practice, for any particular dataset, convergence problems can typically be resolved by selecting a different optimizer or making changes to the settings for the optimization routine, so the convergence rates as given only apply to the default settings.

At the same time, we should point out that the coverage rate of the model did fall slightly below the nominal 95% level in the majority of conditions when all variance components were in fact non-zero (see Figure 2b, rightmost panel). A similar issue, but for a simpler model with only between- and within-study variance components (i.e. model

5 in our simulation), was also recently pointed out by Song et al. (2020). Improved methods based on a t-distribution with various approximations for the degrees of freedom have been proposed and studied extensively in the context of the standard random-effects model (e.g. Sanchez-Meca & Marin-Martinez, 2008) and mixed-effects models in general (e.g. Luke, 2017). Following Nakagawa et al. (2021), we actually based the confidence interval on a t-distribution with $N_{\rm studies}-1$ as the degrees of freedom (as an improvement to using a confidence interval based on a standard normal distribution), although this was apparently not conservative enough, presumably due to the additional dependency among the effect sizes introduced by the phylogeny. Further work will be needed to find an even better approximation to the degrees of freedom in the present context.

4.2 | Including and testing the phylogenetic effect

Phylogenies play a central role in the context of phylogenetic comparative studies (Blomberg et al., 2003; Freckleton et al., 2002; Ives et al., 2007). An important step in such studies is testing the significance of the 'phylogenetic signal' in some trait of interest. This test is often performed through a statistic such as λ (Pagel, 1999) or K (Blomberg et al., 2003). Although model 9 does not parameterize the phylogenetic effect in this manner, one can derive information from its output that shows its relationship to the λ statistic. In particular, Pagel's λ is a multiplicative factor that is applied to the off-diagonal values of the correlation matrix that represents the phylogenetic relationships (i.e. the A matrix). For example, the variance–covariance matrix for three species would be given by

$$\sigma^2 \left[\begin{array}{ccc} 1 & \lambda a_{12} & \lambda a_{13} \\ & 1 & \lambda a_{23} \\ & & 1 \end{array} \right],$$

while the decomposition of the species-level heterogeneity in model 9 implies the variance–covariance matrix

$$\sigma_{n}^{2} \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} + \sigma_{p}^{2} \begin{bmatrix} 1 \ a_{12} \ a_{13} \\ 1 \ a_{23} \\ 1 \end{bmatrix} = \left(\sigma_{n}^{2} + \sigma_{p}^{2}\right) \begin{bmatrix} 1 \ \left(\frac{\sigma_{p}^{2}}{\sigma_{n}^{2} + \sigma_{p}^{2}}\right) a_{12} \ \left(\frac{\sigma_{p}^{2}}{\sigma_{n}^{2} + \sigma_{p}^{2}}\right) a_{13} \\ 1 \ \left(\frac{\sigma_{p}^{2}}{\sigma_{n}^{2} + \sigma_{p}^{2}}\right) a_{23} \end{bmatrix},$$

and hence $\sigma^2 = \sigma_n^2 + \sigma_p^2$ and $\lambda = \sigma_p^2 / (\sigma_n^2 + \sigma_p^2)$ (see also Freckleton et al., 2002; Lynch, 1991). Hence, $\sigma_n^2/(\sigma_n^2 + \sigma_n^2)$ indicates the degree of the phylogenetic signal in the overall variance sourced from the species. A likelihood ratio test of H_0 : $\sigma_n^2 = 0$ can be easily performed by comparing $X^2 = -2(II_7 - II_9)$ against a chi-squared distribution with one degree of freedom, where II_7 and II_9 are the (restricted) log likelihoods of models 7 and 9, respectively. However, we do not advocate making changes to the model based on this test (i.e. by dropping the phylogenetic species random effect from the model if the test is not significant), since making changes to an a priori chosen model based on the data at hand affects the statistical properties of all inferential methods in unknown and unpredictable ways. Finally, we note that the (asymptotic) null distribution of the likelihood ratio test statistic is actually more complex than simply a chi-squared distribution with one degree of freedom, a result of the parameter being on the boundary of the parameter space under the null distribution (Self & Liang, 1987). The appropriate reference distribution for this test in the present context remains to be determined.

4.3 | Estimating the non-phylogenetic and phylogenetic variance

Given the informative nature of these two variance components, it is essential to estimate their true values accurately to properly account for the sources of heterogeneity and dependency in the data. We found that model 9 was usually able to estimate these components with little to no bias, but should note that the model struggles to separate the non-phylogenetic and phylogenetic species effects when phylogenetic relationships are weak. In essence, the two sources of variability then start to collapse into one, with a total variance of $\sigma_n^2 + \sigma_p^2$. The way this total variance is then distributed into the two estimates is in essence arbitrary and can depend on the starting values or other settings of the model fitting algorithm. Therefore, we would caution against the use of model 9 when phylogenetic relationships are weak. As a rough guideline, for $\alpha = 0.5$, the mean correlation in the A matrix (excluding the diagonal) is around 0.2 and hence a lower mean correlation would call into question the trustworthiness of the estimates of σ_n^2 and σ_n^2 .

Some meta-analyses in ecology and evolution have used model 11 to reduce model complexity (e.g. Garamszegi et al., 2012; Moore et al., 2016). Our results indicate that this approach cannot be recommended. As we increased the value of $\sigma_{n'}^2$, the bias in the phylogenetic variance component inflated massively in this simplified model (Figure 4b). As a result, the relevance of the phylogeny could be greatly overestimated. In addition, the confidence interval for the overall mean then becomes extremely conservative with coverage rates at or very close to 100%. This in turn implies a loss of efficiency for estimating the overall mean and a loss of power for testing H_0 : $\mu=0$. The illustrative example also shows this phenomenon.

5 | CONCLUSIONS

For the simulation study, we used a 'generic' effect size measure, that is, we directly simulated the sampling errors from a normal distribution and treated the sampling variances (i.e. the \mathbf{v}_{ij} values) as known. These conditions only apply asymptotically to measures typically used in practice (e.g. standardized mean differences, response ratios, correlation coefficients, risk/odds ratios). The present results therefore reflect the performance of the various models under idealized conditions (i.e. when the sample sizes of the individual studies are sufficiently large such that the sampling distributions of the estimates are indeed approximately normal and any inaccuracies in the estimated sampling variances are negligible). Although such ideal conditions are rare in practice (Hillebrand & Gurevitch, 2014; Pappalardo et al., 2020), the advantage of using a generic measure is that we were able to identify problems that are inherent to certain models and not (potentially) a consequence of violations to the model assumptions (i.e. if a particular model performs poorly for a measure that violates model assumptions, we do not know whether the poor performance is attributable to deficiencies of the model itself or a consequence of model assumptions being violated). On the other hand, it remains to be determined how well the phylogenetic multilevel model performs when the effect sizes are generated based on the exact distributional assumptions underlying specific

393

Also, an issue we did not tackle in the present simulation study is the influence of the distribution of the different species over the simulated studies. In particular, concerns may arise when many of the primary studies included in a meta-analysis have examined only a single or closely related species. This may make it difficult to accurately estimate and differentiate between the study- and the species-level variance components. We did not generate conditions to specifically simulate such scenarios; thus, this issue still remains to be investigated in future simulation studies.

Therefore, at least for the moment, the present results suggest that model 9 is the most appropriate tool for conducting a multispecies meta-analysis in ecology and evolution (unless the phylogenetic relationships are weak, in which case model 7 may be preferable). For the vast majority of conditions examined, it provides approximately unbiased estimates of the variance components and the overall mean and a confidence interval for the latter with a close to nominal coverage rate. Therefore, we recommend that meta-analysts in ecology and evolution use the phylogenetic multilevel model as the de facto standard when analysing multi-species datasets.
