Abstract.—Heterozygosity-fitness correlations (HFCs) have been reported in populations of many species. We provide evidence for a positive correlation between genetic variability and growth rate at 12 allozyme loci in a catadromous marine fish species, the European eel (*Anguilla anguilla* L.). More heterozygous individuals show a significantly higher length and weight increase and an above average condition index in comparison with more homozygous individuals. To a lesser extent, six microsatellite loci show a similar pattern, with positive but not significant correlations between heterozygosity and growth rate. The HFCs observed could be explained by an effect of either direct allozyme overdominance or associative overdominance. Selection affecting some of the allozyme loci would explain the greater strength of the HFCs found at allozymes in comparison with microsatellites and the lack of correlation between MLH at allozymes and MLH at microsatellites. Associative overdominance (where allozyme loci are merely acting as neutral markers of closely linked fitness loci) might provide an explanation for the HFCs if we consider that allozyme loci have a higher chance than microsatellites to be in linkage disequilibrium with fitness loci.

Key words.—Allozymes, associative overdominance, direct overdominance, growth rate, heterozygosity, microsatellites, selection.

Received June 16, 2004. Accepted November 4, 2004.

Heterozygosity-fitness correlations (HFCs), the correlation between heterozygosity observed at marker loci and fitness-related traits such as growth, survival, fecundity, or developmental stability, have been under study for decades in populations of many species. Positive HFCs have been reported in organisms as diverse as plants (Schaal and Levin 1976; Ledig et al. 1983), marine bivalves (Zouros et al. 1980; Koehn and Gaffney 1984), crustaceans (Bierne et al. 2000), amphibians (Pierce and Mitton 1982), salmonids (Leary et al. 1984; Danzmann et al. 1987; Thelen and Allendorf 2001), and mammals (Slate and Pemberton 2002; Hildner et al. 2003). Null results are likely to be underrepresented in literature (Hansson and Westerberg 2002). The correlation between genetic variability and fitness components as reflected by molecular marker heterozygosity in natural populations usually accounts for a small percentage (1–5%) of the observed phenotypic variance (David 1998).

The first HFCs were observed in studies using allozyme markers, which led to the hypothesis of direct overdominance, where the correlation is due to a direct heterozygous genotype advantage at allozyme loci compared to the corresponding homozygous genotypes. It has been proposed that heterozygotes at allozyme loci might have an intrinsically higher fitness than homozygotes, which would be related to lower energy consumption and greater metabolic efficiency (Mitton 1993).

The observation of positive HFCs with putative neutral DNA markers proves that at least some correlations are not due to the direct effect of the marker genes but to the genetic association between the neutral markers and fitness genes, resulting in associative overdominance (David 1998). When marker loci are not directly responsible, the observed correlation can be either due to the effect of linkage disequilibrium restricted to a narrow chromosomal section affecting closely linked fitness loci (local effect) or due to partial in-

breeding caused by the nonrandom association of diploid genotypes in zygotes (general effect) (David et al. 1995).

Few studies correlating heterozygosity and growth have been carried out in fish, mainly due to the difficulty in rearing experiments, especially for marine species. In salmonids, Danzmann et al. (1987) found a positive correlation between allozyme heterozygosity and growth (length or weight up to six months) in cultured rainbow trout (*Oncorhynchus mykiss*), suggesting that heterozygotes have enhanced growth rates compared to more homozygous individuals. Nevertheless, salmonids seem to produce different HFCs at different life stages, and negative correlations were found between (1) allozyme variation and length at one year, and (2) length and weight at maturation (Ferguson 1990, 1992). Pogson and Fevolden (1998) examined the relationships between growth and the degree of individual heterozygosity at 10 nuclear RFLP loci in two natural populations of Atlantic cod (*Gadus morhua*), using a rough measure of growth (size at age). A significant positive correlation was found in one population, supporting the hypothesis that neutral DNA markers can detect HFCs.

The species of interest in this study is the European eel (*Anguilla anguilla* L.; Anguillidae; Teleostei), a catadromous fish species with a particularly complex life cycle, which moves between marine (spawning, larval phase, and maturation) and freshwater (feeding, growth, and maturation) environments. After spawning in the Sargasso Sea, larvae (leptocephali) migrate with the Gulf Stream and North Atlantic Drift Current to the shores of Europe and North Africa, where they metamorphose into glass eels upon reaching the continental shelf. Glass eels move into freshwater systems (rivers, lagoons, or lakes), where they feed for up to 25 years (on average, 7–8 years for males and 11 years for females) before metamorphosing into silver eels and migrating back to the Sargasso Sea, where they spawn once and die (Tesch 2003).

Recruitment abundance of European eel has declined dra-

TABLE 1. Summary of genetic samples of farmed glass eels, *Anguilla anguilla*, including sampling date, number of individuals analyzed (*n*), mean length (*L*) and mean weight (*W*). Standard deviation in parentheses.

ROY101	1	December 2001	100	71.69 (3.80)	0.41 (0.07)
ROY102	1	December 2002	100	233.04 (69.80)	29.16 (31.95)
ROY201	2	February 2002	100	70.36 (4.47)	0.29 (0.07)
ROY202	2	February 2003	100	241.34 (87.74)	43.37 (44.80)
ROY2F	2	February 2003	50	612.9 (41.1)	602.2 (117.5)

matically in recent decades, jeopardizing the future of the species (Dekker 2003). A better understanding of crucial aspects of its biology, including genetic diversity, may promote effective measures to protect the species. In the case of European eels, no previous studies have been carried out to correlate individual growth and genetic variability. Despite progress in artificial propagation, completion of the European eel life cycle in captivity is not possible yet (Tesch 2003). Alternatively, fattening farms dedicated to the growth of stocked glass eel (varying from postlarvae having completed the leptocephalus metamorphosis to the full pigmentation stage), are readily available in many coastal regions of southern and western Europe. There is a long history of stocking and extensive rearing of eels in ponds, offering an adequate setting for growth experiments (Tesch 2003). When growth is tested under artificial conditions, it must be taken into account that environmental stress might enhance HFCs (Danzmann et al. 1988) and that HFCs seem to decrease with age (David 1998).

The aim of this study is to identify the existence of HFCs in European eels to evaluate genetic variability and selection in cultured eel populations and to assess the contribution of genetic and environmental factors in the growth of the species. At the same time, such experiments provide a model for natural populations of European eel and for other fish species. The association between heterozygosity and two phenotypic measures of growth (length and weight increase) was tested in two groups of farmed European eel individuals using 13 allozyme and six microsatellite markers. In case of direct overdominance, HFCs should not be expressed at putative neutral markers (microsatellites) but only at markers affected by natural selection (allozymes). Under the hypothesis of associative overdominance, an apparent advantage observed at heterozygous individuals would be independent of the genetic marker used. Since linkage is not limited to allozymes, a similar HFC would be expected using either allozyme or microsatellite markers. Both hypotheses are not mutually exclusive since natural selection might not be acting equally across all allozyme loci. Besides, despite the usual interpretation that microsatellites evolve neutrally, recent studies have documented the functional role of microsatellites in gene regulation, chromatin organization, cell cycle and DNA metabolic processes (Li et al. 2002).

MATERIALS AND METHODS

Glass eel individuals collected in the mouth of the river Adour (southwestern France) were transferred and raised in a closed recirculation system at the eel farm at Royaal BV (The Netherlands). Two batches of glass eels, collected in December

2001 (batch 1; ROY101) and February 2002 (Batch 2; ROY 201), were monitored for one year. A subsample of 100 individuals was collected from each batch at the start of the experiment and after one year in the tanks (ROY102 and ROY202) for genetic analyses (Table 1). Once measured, individuals were split in two, with the tail kept in ethanol for microsatellite analysis and the rest of the body kept frozen at -80°C for allozyme analysis. Genetic analysis also included a subsample of 50 individuals from batch 2 (ROY2F), which were regarded as fast-growth individuals due to their exceptional growth rate after one year in the tanks in the same conditions as the rest of the individuals (mean length: 612.9 ± 41.1 mm, mean weight: 602.2 ± 117.5 g).

Allozyme Electrophoresis

A total of 450 individuals (Table 1) were analyzed for protein variation using cellulose acetate gel electrophoresis (CAGE; Harris and Hopkinson 1976; Richardson et al. 1986). Tissue extraction, electrophoresis and procedures for visualizing proteins, and buffer systems used (Tris glycine [TG] and Tris malate [TM]) are described in Maes and Volckaert (2002). Nine enzymatic systems were examined: aspartate aminotransferase (*AAT-1**, *AAT-2**, *AAT-3**, EC 2.6.1.1, TM), alcohol dehydrogenase (*ADH**, EC 1.1.1.1, TG), glucose-6-phosphate isomerase (*GPI-1**, *GPI-2**, EC 5.3.1.9, TG), L-iditol dehydrogenase (*IDDH**, EC 1.1.1.14, TG), isocitrate dehydrogenase (*IDHP**, EC 1.1.1.42, TM), malate dehydrogenase (*MDH-2**, EC 1.1.1.37, TM), mannose-6-phosphate isomerase (*MPI**, EC 5.3.1.8, TG), phosphogluconate dehydrogenase (*PGDH**, EC 1.1.1.44, TM), and phosphoglucomutase (*PGM**, EC 5.4.2.2, TG). Genetic nomenclature followed the suggestions of Shaklee et al. (1990). Allele assignment was carried out comparing the relative distance with the most common allele (*100).

Microsatellite Analysis

DNA was extracted in a subsample of 60 of the 100 individuals from each batch at the start of the experiment and after one year in the tanks, and 50 fast-growth individuals. Minute sections of tissue from ethanol-preserved glass eels were digested in a lysis buffer containing 100 l TE buffer, 7 μl 1M DTT (dithiothreitol) solution pH 5.2 (diluted in 0.08M NaAc) and 5 μl proteinase K solution (10 mg.ml $^{-1}$) for at least 4 h at 56°C . After incubation at 96°C for 10 min, samples were centrifuged at 13,000 rpm for 11 min; the supernatant was stored at -20°C for further analysis. Genotypes were examined at six dinucleotide repeat microsatellite loci: *Aan 01*, *Aan 03*, *Aan 05* (Daemen et al. 2001), *Aro 063*, *Aro*

095, and *Ang 151* (Wirth and Bernatchez 2001). Loci were amplified in two separate multiplexes. Multiplex polymerase chain reaction (PCR) reactions consisted of 1× PCR buffer (supplied with polymerase), 1.5 mM MgCl₂, 80 μM dNTP, 0.4 μM (on average) fluorochrome labeled forward and non-labeled reverse primer, 0.5 U Goldstar *Taq* polymerase (Eurogentec, Seraing, Belgium) and 1 μl DNA template. DdH₂O was added up to 25 μl. PCR cycling conditions were as follows: 5 min at 94°C, 24 cycles of 30 sec at 94°C, 30 sec at 57°C, and 30 sec at 72°C, and final elongation for 8 min at 72°C. PCR products were visualized on an automated sequencer (LICOR 4200) using a molecular ladder (Westburg, Leusden, The Netherlands) to quantify allele sizes. Fragment data were analyzed using Gene ImagIR version 4.03 (Scanalytics Inc., Fairfax, VA).

Data Analysis

All individuals were measured for standard length (L) and body weight (W). Length and weight increase were calculated as the difference between individual length and weight after one year in the tanks and mean length and weight after arriving in the facilities. Ricker's (1975) condition factor ($CI = 1000(W/L^b)$) was calculated for each individual, where L is standard length in mm, W is body weight in mg and b is the slope from the log length–log weight regression for all samples. The condition factor is based on the analysis of length–weight data, assuming that heavier individuals at a given length are in a better condition. Additionally, the relative condition factor (k) has been calculated as described in Le Cren (1951). $k = W/\hat{W}$ compares the observed (W) and expected (\hat{W}) weight of each individual, where expected weight is obtained using the length–weight regression ($W = aL^b$) of each individual. Differences in morphometric measures among groups were tested using an analysis of variance (ANOVA).

Within-sample genetic variation was assessed by observed heterozygosity per locus (H_o), level of polymorphism using the 95% criterion ($P_{0.05}$), and mean and total number of alleles using GENETIX version 4.02 (Belkhir et al. 1999). Values among groups were compared by ANOVA. Deviations from Hardy-Weinberg equilibrium, genotypic associations for all possible pairs of loci in each sample, and differences in allele frequencies among samples were tested using GENEPOP version 3.1d (Raymond and Rousset 1995). Significance levels for multiple simultaneous comparisons were adjusted using the sequential Bonferroni technique (Rice 1989). Patterns of variation among samples were assessed by hierarchical gene diversity analysis as implemented in GENETIX version 4.02 (Belkhir et al. 1999).

Individual multilocus heterozygosity (MLH) was calculated as the proportion of loci that are heterozygous (corrected for nonscored loci). MLH among groups was compared using ANOVA. In the case of microsatellite loci, the squared difference in repeat units between two alleles in an individual at a given locus (d^2) averaged over all loci (mean d^2) was calculated following Coulson et al. (1998). Mean d^2 is an alternative method to MLH to infer fitness differences between individuals; in addition to taking into account whether individuals are homozygotes or heterozygotes, it also con-

siders the differences in allele size in heterozygous individuals. Coltman et al. (1998) suggested that mean d^2 provides a better measure of individual genetic variability than MLH for microsatellite data. Outbreeding mean d^2 (calculated in the same way as mean d^2 but excluding homozygous loci in each individual) and standardized mean $d^2_{\text{var}(d^2)}$ (the average d^2 at each locus scaled by the variance of d^2 at that locus) were calculated for each individual as described by Hedrick et al. (2001).

All data were checked for normality and a logarithmic transformation was conducted if necessary before parametric statistical analysis. Regression analysis (Pearson's correlation) was performed between individual heterozygosity (MLH and all calculations of d^2) values and growth estimators (length increase, weight increase, condition index, and relative condition index) to test for possible HFCs. When fast-growth individuals were included in the analysis, Spearman's correlation was used since variables did not approximate a normal distribution following logarithmic transformation. All analyses were performed in STATISTICA version 6.0 (Statsoft Inc. Tulsa, OK). Significance for all statistical tests was taken as $P = 0.05$.

RESULTS

A comparison between the newly arrived batches 1 and 2 showed no significant differences in length and weight (Table 1). After one year at the farm, a substantial range of sizes was observed in both batches. In batch 1, average length was 233.04 ± 69.80 mm, with a maximum length of 444 mm and a minimum length of 135 mm. Differences were not significant in comparison with batch 2, with an average length of 241.34 ± 87.74 mm ranging from 110 to 433 mm. Larger differences were observed in the weight distribution, with individuals from batch 2 (mean weight: 43.37 ± 44.80 g; maximum weight: 183.2 g) being heavier than individuals from batch 1 (mean weight: 29.16 ± 31.95 g; maximum weight: 136.2 g), although differences were not significant. Individuals from batch 1 showed an average increase of 167.58 ± 66.83 mm and 29.29 ± 31.48 g, whereas individuals from batch 2 showed an average increase of 176.18 ± 84.97 mm and 44.45 ± 44.62 g. Increases of both batches were not significantly different.

To correlate genetic variability with growth, the samples from batch 1 and 2 that had spent one year at the farm (ROY102 and ROY202) were split for the analysis into small (<40 g, $n = 136$) and large individuals (40–200 g, $n = 64$), and compared with the fast-growth individuals (500–800 g, $n = 50$). Differences in length and weight among groups were statistically significant.

Allozymes

The nine enzymatic systems examined resulted in 12 polymorphic loci. Overall tests for Hardy-Weinberg proportions with all polymorphic loci, and for linkage disequilibrium among all loci showed no significant departures from expected values. When observed heterozygosities were compared between growth groups, the group of small individuals presented lower heterozygosities ($H_o = 0.192 \pm 0.217$) than the group of large individuals ($H_o = 0.217 \pm 0.200$), whereas

TABLE 2. Values of observed heterozygosity (H_o), level of polymorphism (P_{95}) and mean number of alleles (MNA) at all allozyme and microsatellite loci for small (<40 g), large (40–200 g) and fast-growth (500–800 g) individuals. Standard error in parentheses.

* $P < 0.05$.

the highest heterozygosities were observed in the fast-growth individuals ($H_o = 0.235 \pm 0.225$; Table 2). Differences in observed heterozygosities between groups were statistically significant ($P < 0.05$). The group of fast-growth individuals presented higher values of observed heterozygosity for most of the loci in comparison with small and large individuals, including *AAT-1**, *GPI-1**, *GPI-2**, *IDHP**, *MPI**, *PGDH** and *PGM** (Table 2). Additionally, polymorphism was also higher in fast-growth individuals (0.692) than in large (0.615) and small (0.539) individuals.

To correlate genetic variability and growth at the individual level, multilocus heterozygosity (MLH) was calculated for each individual (Fig. 1). When pooling all individuals (combining batches 1 and 2), a highly significant positive association was observed between MLH and length increase ($r = 0.177$; $P = 0.005$) and between MLH and weight increase ($r = 0.164$; $P = 0.009$). Similarly, when the fast-growth individuals were not included in the analysis, a significant correlation was found between MLH and length increase ($r = 0.153$; $P = 0.030$), and MLH and weight increase ($r = 0.143$; $P = 0.044$). In batch 1, the correlations between MLH and length increase ($r = 0.065$; $P = 0.518$) and between MLH and weight increase ($r = 0.066$; $P = 0.517$) were positive but not statistically significant. By contrast, a significant correlation was found in batch 2 between MLH and length increase ($r = 0.240$; $P = 0.016$), and MLH and weight increase ($r = 0.230$; $P = 0.021$).

Multilocus heterozygosity at allozymes explained 3.1% of the variation in length increase and 3.3% of the variation in weight increase. When mean MLH was calculated for each growth group, slow individuals presented the lowest MLH (0.188 ± 0.087) in comparison with large individuals (0.216 ± 0.102), and the greatest MLH was found in fast-growth individuals (0.229 ± 0.108). When HFCs were tested within growth groups, no significant associations were observed between MLH and growth rate for either small, large or fast growth individuals.

Ricker's condition index (CI) was calculated as $1000(W/L^{3.48})$ for each individual, using the length-weight regression

for all samples to correct for population effects. The correlation found between MLH and condition factor was positive but not significant when pooling all samples ($r = 0.045$; $P = 0.484$), but negative when considering the batches separately or when excluding fast-growth individuals in the analysis (Fig. 1). When using the relative condition index (k), significant correlations were found for all pooled individuals ($r = 0.157$; $P = 0.013$) and for batch 2 ($r = 0.215$; $P = 0.032$), and a positive but not significant correlation for batch 1 ($r = 0.063$; $P = 0.537$).

Examination of individual loci suggests that the effect of allozyme heterozygosity on growth is attributed to most of the loci examined. Of 10 loci (in which all genotypes were sufficiently represented), heterozygotes presented a greater length than homozygotes at 10 loci and a greater weight and relative condition at nine loci (Table 3). Differences between homozygotes and heterozygotes were maximal at *GPI-1** and *MPI**, with a difference of 5.5 cm in mean length and >70 g in mean weight (70.5 g at *GPI-1** and 80.2 g at *MPI**). These were the only statistically different comparisons ($P < 0.05$).

Microsatellites

Tests for Hardy-Weinberg proportions with all polymorphic loci, and for genotypic disequilibrium among all loci, showed no significant departures from expected values. In contrast to allozyme data, the highest heterozygosities were found in large individuals ($H_o = 0.753 \pm 0.276$) in comparison with small ($H_o = 0.711 \pm 0.253$) and fast-growth ($H_o = 0.726 \pm 0.275$) individuals; differences were not statistically significant (Table 2). Fast-growth individuals only presented a higher (but not significant) heterozygosity at one of the six microsatellite loci examined (*Ang 151*) in comparison with the other growth groups. Small individuals also presented a higher mean number of alleles (18.167) in comparison with large (11.333) and fast-growth (13.667) individuals.

A small positive effect of microsatellite heterozygosity on

* $P < 0.05$.

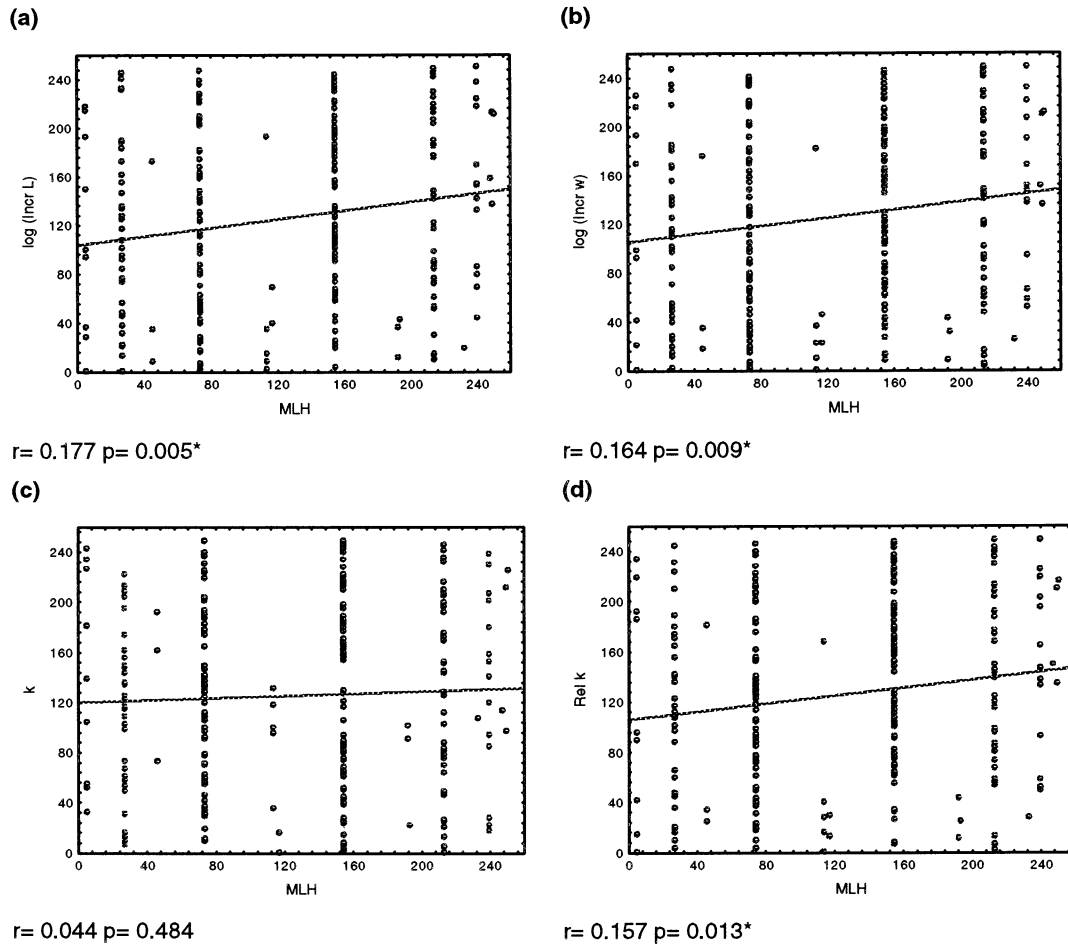

FIG. 1. Spearman rank correlation of multilocus heterozygosity (MLH) versus (a) length (cm) increase, (b) weight (g) increase, (c) condition index (k), and (d) relative condition index (rel k) at 12 allozyme loci in all *Anguilla anguilla* individuals.

growth was observed in most loci examined, although no comparisons were statistically significant. Heterozygotes presented a greater length and weight than homozygotes at four of six loci examined and a higher relative condition at five loci (Table 3). Differences between heterozygotes and homozygotes were maximal at *Aro 095* (4.14 cm in length; 58.6 g in weight) and *Ang 151* (3.15 cm in length; 54.1 g in weight).

Individual MLH showed a positive correlation between growth rate (measured as length and weight increase) and heterozygosity at six microsatellite loci, although this association was not as strong as found for the allozyme markers (Fig. 2). Positive but not significant correlations were observed between MLH and length increase ($r = 0.142$; $P = 0.070$), and MLH and weight increase ($r = 0.145$; $P = 0.063$), and when fast-growth individuals were not included in the analysis (MLH and length increase: $r = 0.163$; $P = 0.081$; MLH and weight increase: $r = 0.166$; $P = 0.076$). In batch 1, correlations were positive but not significant between MLH and length increase ($r = 0.237$; $P = 0.076$) and significant between MLH and weight increase ($r = 0.264$; $P = 0.047$). In batch 2, correlations were positive but not significant (MLH and length increase: $r = 0.037$; $P = 0.786$; MLH and weight increase: $r = 0.037$; $P = 0.782$). Multilocus heterozygosity at microsatellite loci explained 1.0% of the variation in length increase and 1.3% of the variation in weight increase.

When mean MLH was calculated for each growth group using microsatellite loci, large individuals presented the largest MLH (0.751 ± 0.146) in comparison with fast-growth (0.733 ± 0.166) and slow (0.703 ± 0.158) individuals. No HFCs were observed within growth groups.

Negative associations were observed between MLH and Ricker's condition index in all possible comparisons. Using the relative condition index, positive but not significant correlations were observed for batch 1 ($r = 0.117$; $P = 0.137$), batch 2 ($r = 0.032$; $P = 0.815$) and when pooling all individuals ($r = 0.152$; $P = 0.052$). The logarithmic transformation of mean d^2 was negatively correlated to growth rate (Fig. 3). Negative associations were found between mean d^2 and length increase ($r = -0.045$; $P = 0.557$), weight increase ($r = -0.050$; $P = 0.537$), condition index ($r = -0.058$; $P = 0.478$) and relative condition index ($r = -0.055$; $P = 0.494$), respectively. Similar negative correlations were obtained when homozygous loci in each individual were excluded (outbreeding mean d^2) or when mean d^2 was standardized at each locus by the variance of d^2 (mean $d_{\text{var}(d^2)}^2$). When testing the association between genetic variation at allozymes and microsatellite markers, a nonsignificant neg-

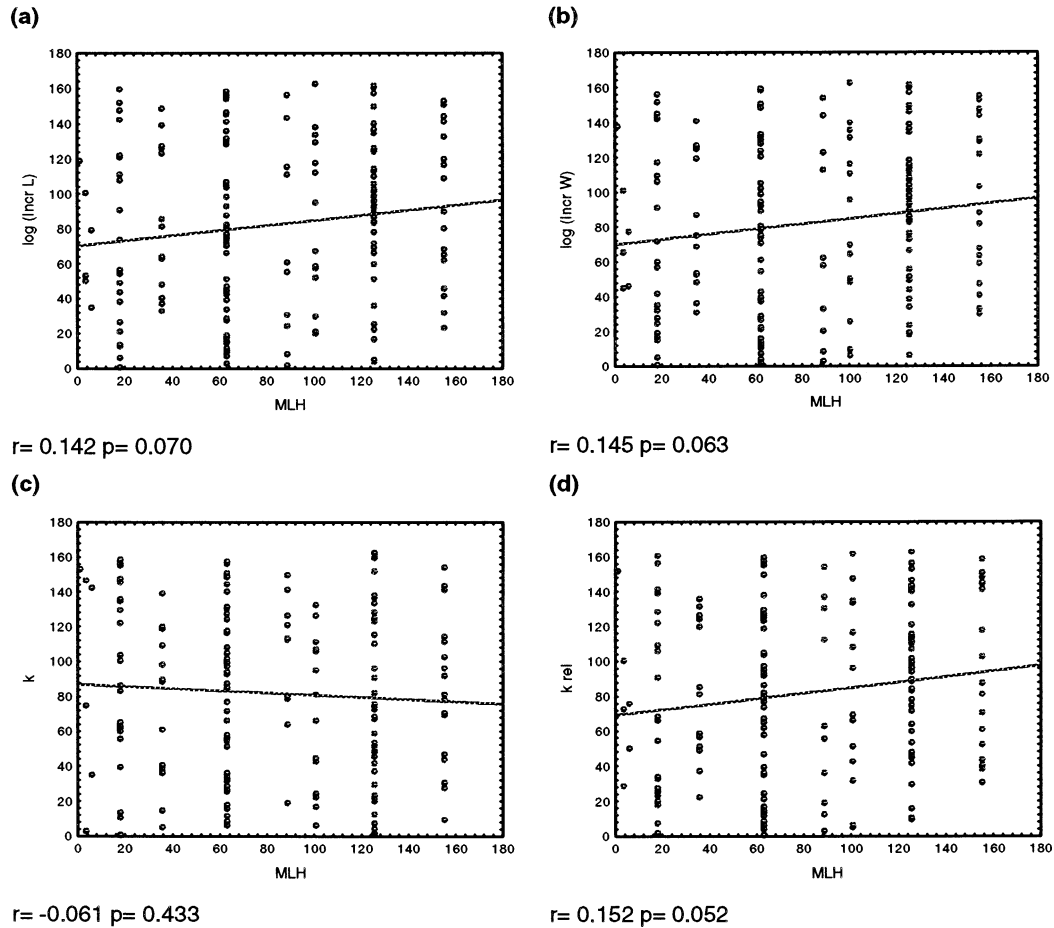

FIG. 2. Spearman rank correlation of multilocus heterozygosity versus (a) length (cm) increase, (b) weight (g) increase, (c) condition index, and (d) relative condition index at six microsatellite loci in all individuals.

ative correlation was found between individual MLH at allozyme loci and individual MLH at microsatellite loci (Fig. 4).

DISCUSSION

Evidence for Heterozygosity-Fitness Correlation in the European Eel

We clearly show a positive correlation between heterozygosity at allozyme loci and growth rate; more heterozygous individuals presented a higher length and weight increase and a greater relative condition index in two separate batches of farmed European eels. The stronger correlations observed in batch 2 in comparison with batch 1 might be related to their greater variation in length and weight; differences in growth rate should be easier to detect in such conditions. At microsatellite loci, a general pattern was observed that individuals with a larger growth rate mostly presented higher heterozygosities. Correlations were positive but not significant, and HFCs at microsatellites cannot be considered as strong as HFCs at allozymes. Multilocus heterozygosity at allozymes also explained more variation in length and weight increase (3%) than MLH at microsatellites (1%) in multiple regressions. Because heterozygosity in the European eel explains less than 5% of the individual variation in growth rate, the

large fraction of unexplained variation in growth rate is partitioned between environmental effects, genetic factors other than the loci studied, and epistatic interactions. Similar correlation values have been reported in previous HFC studies, usually accounting for a small proportion of the observed phenotypic variance (3–6%; Britten 1996). A meta-analysis of correlations between phenotypic variation and genetic variation revealed that the strength of the associations is generally weak (mean $r < 0.10$), with a mean r of 0.0274 for MLH and 0.0156 for mean d^2 , respectively (Coltman and Slate 2003). Examining HFCs in fish, multilocus allozyme heterozygosity explained more than 10% of the total variance of the condition factor in rainbow trout (*Oncorhynchus mykiss*; Thelen and Allendorf 2001). In the positive correlations between genetic variation (both microsatellite heterozygosity and d^2) and four reproductive fitness-related traits in chinook salmon (*Oncorhynchus tshawytscha*), regressions explained between 6% and 8% of the variance (Heath et al. 2002).

Our results show that heterozygosity at allozyme and microsatellite loci, albeit scored for an unequal number of loci, has a different effect on the individual phenotype and support the view that natural selection does not affect allozymes and microsatellites similarly. A negative correlation was observed between individual MLH at allozymes and individual MLH at microsatellites (Fig. 4), indicating that a high level of

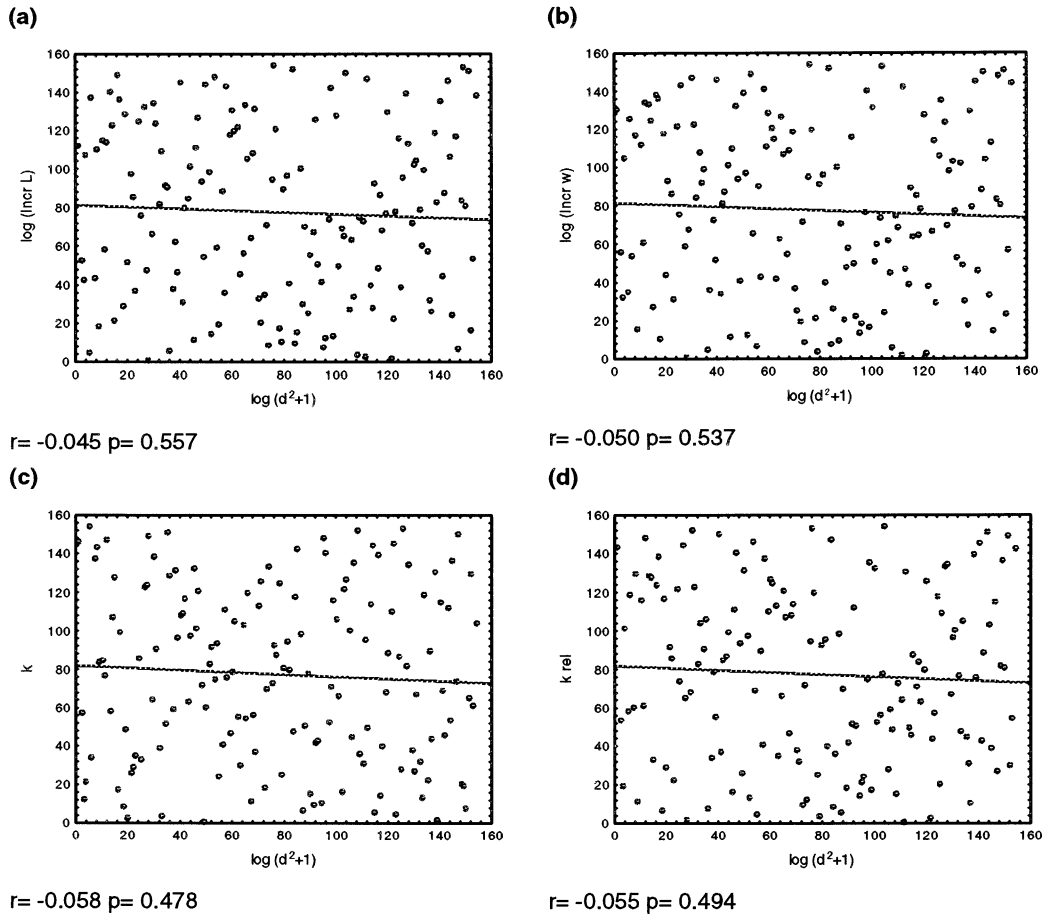

FIG. 3. Regression of mean d^2 versus (a) length (cm) increase, (b) weight (g) increase, (c) condition index, and (d) relative condition index at six microsatellite loci in all individuals.

FIG. 4. Regression of multilocus heterozygosity (MLH) at 12 allozyme loci versus MLH at six microsatellite loci in all individuals.

genetic variability at allozyme loci does not necessarily correspond with a high genetic variation at microsatellite loci. In fish, Thelen and Allendorf (2001) examined the relationship between MLH and condition factor at 10 allozyme and 10 microsatellite loci in 217 farmed rainbow trout (*O. mykiss*). Although more heterozygous individuals at allozyme loci showed a significantly higher condition factor, increased heterozygosity at microsatellite loci was not associated with a higher condition. More recently, Borrell et al. (2004) reported a positive correlation between heterozygosity and fluctuating asymmetry, length, and weight in two samples of Atlantic salmon (*Salmo salar*) with different timings of first active feeding at six allozyme loci but not at eight microsatellite loci.

Positive correlations were observed in our study between MLH and all growth measures except condition. Weight is highly variable among eel populations; optimal feeding conditions may cause an eel's weight to be twice that of another eel of equal length (Tesch 2003). This is especially valid in aquaculture and might explain the lack of correlation between MLH and condition observed in our study. On the other hand, relative condition mostly reflects changes in weight regardless of changes in length. Hence, the positive association between MLH and relative condition is a direct consequence

of the positive correlation observed between MLH and weight.

Regarding the performance of MLH and mean d^2 , our results are concordant with the meta-analysis of published and unpublished HFCs carried out by Coltman and Slate (2003), where correlations reported for mean d^2 were smaller than those reported for MLH. Contrasting with the positive correlation between MLH and growth in our study, the negative association between mean d^2 and growth in the European eel (Fig. 3) suggests that mean d^2 might not be an adequate estimator of genetic variability. Positive associations between mean d^2 and fitness traits have been reported in species with high inbreeding coefficients (Coltman et al. 1998; Coulson et al. 1998), where mean d^2 refers to the relatedness of individuals and not genetic variation. In the absence of inbreeding, which is typical for species with large population sizes, high migration rates, and lack of population substructuring, mean d^2 does not necessarily reflect genetic variation. This explains the negative relation in our study between mean d^2 and growth rate.

Support for the Direct Overdominance Hypothesis

A prediction of the direct overdominance hypothesis is that only heterozygosity scored at selection-sensitive markers should correlate with fitness traits, whereas no relationship should be expected at neutral markers. This contrasts with the associative overdominance hypothesis, in which HFCs are not specific to the type of genetic marker used. In our study, both markers showed positive correlations between the degree of heterozygosity and growth rate, but only significantly so at allozymes. Similarly, fast-growth individuals presented significantly higher heterozygosities than other individuals at allozymes but not at microsatellites. Allozymes produced a more significant and consistent association than microsatellites, thus providing evidence for the direct overdominance hypothesis as an explanation for the HFCs observed. Nevertheless, it must be taken into account that although microsatellites are usually considered evolutionarily neutral DNA markers (Schlötterer and Wiehe 1999), recent evidence indicates otherwise and at least some microsatellites are functionally important and may not be neutral (Li et al. 2002). Pogson and Zouros (1994) proposed that under the associative overdominance hypothesis recalculation of MLH combining both allozymes and microsatellites loci would result in stronger HFCs than in each set of markers independently. In our study, correlations with the combined set of 18 loci were identical to the ones obtained with allozyme data, with an apparent lack of effect of microsatellite loci.

Selection affecting some of the allozyme loci would explain the stronger HFCs at allozymes in comparison with microsatellites, and the lack of correlation between MLH at allozymes and MLH at microsatellites. At allozymes, more heterozygous individuals present an intrinsically higher fitness due to increased biochemical efficiency in comparison with more homozygous individuals (Mitton 1993, 1997). Model organisms like *Drosophila melanogaster* and *Fundulus heteroclitus* have provided clear evidence for selection acting on enzyme polymorphisms in metabolic genes (Eanes 1999). Koehn et al. (1988) reported significant effects of hetero-

zygosity on growth at enzymes involved in metabolic functions such as protein catabolism or glycolysis, whereas genes without significant effect on growth rate code for enzymes with other miscellaneous functions including the pentose shunt, redox balance, or digestion. Metabolic responses to selection are essentially multilocus in nature (reviewed in Eanes 1999). The effects of allozyme heterozygosity on growth are the result of many loci, although not all contribute equally (Pogson and Zouros 1994; Thelen and Allendorf 2001). In the scallop *Placopecten magellanicus*, the mean shell length in heterozygotes was larger than in homozygotes at eight loci, but only significant at two loci (Pogson and Zouros 1994). In our study, positive differences in growth between homozygotes and heterozygotes were observed at almost all loci. Statistically significant values were only obtained when comparing differences in length and weight increase at *GPI** and *MPI**. Both loci are involved in important metabolic functions: mannose-6-phosphate isomerase (MPI) is a preglycolytic enzyme, which supplies carbon skeletons to glycolysis. Glucose phosphate isomerase (GPI) is a main-line glycolytic enzyme that catalyzes the reversible interconversion of d-fructose-6-phosphate and d-glucose-6-phosphate. By contrast, the smallest differences between homozygotes and heterozygotes in growth rate were observed at phosphogluconate dehydrogenase (PGDH), which codes for an enzyme with a secondary metabolic function (pentose shunt). Since PGDH is not involved in protein catabolism or glycolysis, it would play a smaller role in growth.

Alternative Hypothesis: Associative Overdominance

Associative overdominance could provide an explanation for the HFCs in this study if we consider that allozyme loci have a higher chance than microsatellites to be in linkage disequilibrium with fitness loci. A greater mutation rate of microsatellites would cause homozygous genotypes to present identical alleles by state (homoplasy) and not by descent, and therefore are less likely to reflect homozygosity at linked fitness loci. Alternatively, allozyme and microsatellite loci might not have the same distribution in the genome. If allozyme loci are located in richer gene regions and microsatellite loci in poorer gene regions, allozymes would be more likely to be in linkage disequilibrium with fitness loci (Thelen and Allendorf 2001). Little information is available on the distribution of genes in the European eel, although linkage maps in for example salmonids (pink salmon, Lindner et al. 2000; brown trout, Sakamoto et al. 2000) suggest that allozyme and microsatellite loci are found at similar genomic locations. Tóth et al. (2000) reported that, despite microsatellites being less abundant in exons than in noncoding regions, microsatellite distribution in introns and intergenic regions is similar and differs only in the abundance of certain triplets.

The main mechanisms explaining HFCs detected by neutral markers relate to inbreeding due to low effective population sizes or linkage disequilibrium caused by bottleneck/founder events followed by rapid population expansion (Hansson and Westerberg 2002). Glass eel recruitment is estimated at about 2×10^9 individuals per year, although mortality is close to 100% in some areas (Dekker 2000). As in many marine fish

species, anthropogenic impacts (fisheries overexploitation, pollution, habitat loss, and migration barriers) cause populations to decline. Since the 1980s, a steady downward trend has been observed in recruitment of glass eels arriving to the European continent, which is affecting or will shortly affect the continental (yellow and silver eel) stock (ICES 2003). Using a Bayesian approach to infer demographic parameters from microsatellite data, Wirth and Bernatchez (2003) suggested a contemporary effective population size of about $5 \times 10^3 - 10^4$ eels. Despite the population of European eels being possibly at an historical minimum, it would remain large enough not to be affected by inbreeding.

Conclusions and Future Directions

Our results provide sound evidence for a heterozygosity-fitness correlation in farmed European eel individuals. Multilocus heterozygosity is positively correlated with growth, so that more heterozygous individuals at allozyme loci (and to a lesser extent microsatellite loci) show a significantly higher length and weight increase and a higher condition index in comparison with more homozygous individuals. The HFCs observed could be explained by an effect of either direct allozyme overdominance or associative overdominance.

HFCs are expected to decrease or disappear with age since growth and survival differences are maximal early in life (David 1998). It has been proposed that early and late growth may be controlled by different sets of genes (Vaugh et al. 1999). In our study, individuals will be kept in the farm for another year, which will allow us to check for time consistency of the observed HFCs. We intend to estimate genotype-specific survival and possible heterozygosity-viability correlations by analyzing individuals that died after handling and parasite infection, and the influence of grading (early splitting of individuals in size classes) in the association MLH growth.

ACKNOWLEDGMENTS

We thank G. Pogson and three anonymous reviewers for their useful comments on the manuscript. We also thank V. van Ginneken and all the personnel at Royaal BV who assisted us with sampling. Research was funded by the European Union contract EELREP (Estimation of the Reproductive Capacity of European Eel; Q5RS-2001-01836). J. M. Pujolar received a postdoctoral fellowship from the Ministerio de Educación, Cultura y Deporte (Spain). G. E. Maes received a Ph.D. fellowship from the I.WT (Institute for the Promotion of Innovation by Science and Technology) in Flanders.
